Nowadays, all major vehicle manufacturers are developing AVs, either on their own or in cooperation with some other stakeholders. Large technology companies, such as Alphabet (owner of Waymo), Baidu, and Yandex, are also among key stakeholders. Notably, several start-up companies (e.g., Argo AI, Cruise Automation, Aurora) have entered the scene and are often viewed as major drivers of innovation. In addition, providers of key enabling technologies for sensing and processing technologies (e.g., Intel/Mobileye, NVIDIA) play a crucial role.

Categorization of Automated Vehicles

To better define and categorize ADS, several organizations have proposed classification scales. The scale proposed by the Society of Automotive Engineers (SAE) in the SAE J3016 standard (SAE International, 2018) is today the most common. It should, however, be noted that all attempts to classify vehicles into different levels of automation have shortcomings. For example, a vehicle can contain ADS of different automation levels that are used at different occasions. Consequently, it becomes difficult to say that the vehicle belongs to a certain level of automation. A common “workaround” is to specify the operational design domain (ODD) and refer to the conditions under which the ADS operates.

The SAE scale incorporates six levels, ranging from Level 0 (fully manual) to Level 5 (fully automated), see Table 1. Largely simplified, Levels 0–3 mean that a human driver exists in the vehicle and either drives (possibly with the support of the ADS), or is prepared to take over the driving task when the system requests it. Automated vehicles belonging to the lower levels of automation (up to Level 3) are found in several types of mass-produced vehicles today (e.g., Adaptive Cruise Control (ACC), Lane Departure Warning (LDW), Lane Keeping Support (LKS), Blind Spot Detection (BSD)). Level 3 automation is currently under development and is a widely debated topic due to its requirement that the human drivers are ultimately responsible for the driving at the same time as the ADS takes care of the driving and allows them to focus on other activities.

In Levels 4 and 5, an ADS drives the vehicle and the vehicle can also handle the situation when it is not possible to drive automatically. This means that no human driver is needed at those levels. However, a vehicle with automated functions at the higher levels may also be able to drive manually (dual functions). The difference between Levels 4 and 5 is that Level 4 vehicles can only drive in certain traffic situations or in certain areas, while Level 5 vehicles can handle all situations and environments that a physical driver can handle. In practice, Level 4 is referred to as highly automated driving, while Level 5 is fully automated driving.

Technology Behind Automated Driving

Automated driving is enabled by advanced software, powerful data processing units, detailed maps, and an array of sensors that together create a 360-degree living map of the traffic environment around the vehicle. Most stakeholders are relying on a similar combination of lidars, radars, cameras, and ultrasonic sensors, with a few notable exceptions (e.g., Tesla relies on a combination of

Table 1 Automation levels as defined by the SAE standard J3016.

SAE J3016	Level 0	Level 1	Level 2	Level 3	Level 4	Level 5
What does the human in the driver's seat have to do?	You are driving whenever these support features are engaged—even if your feet are off the pedals and you are not steering You must constantly supervise these support features; you must steer, brake or accelerate as needed to maintain safety			You are not driving when these automated driving features are engaged—even if you are seated in “the driver's seat” When the feature request, you must drive These automated driving features will not require you to take over driving		
What do these features do?	These features are limited to provide warnings and momentary assistance	These features provide steering OR brake/acceleration support to the driver	These features provide steering AND brake/acceleration support to the driver	These features can drive the vehicle under limited conditions and will not operate unless all required conditions are met	This feature can drive the vehicle under all conditions	

Source: Based on (SAE International, 2019).

cameras and ultrasonic sensors only). To accommodate a high level of robustness and redundancy, stakeholders are commonly using several sensors (e.g., Waymo's 5th generation of automated driving system, Waymo Driver, incorporates 5 lidars, 4 radars, and 29 cameras (Jeyachandran, 2020)). Using multiple sensors, however, poses integration challenges for system manufacturers. Consequently, several of them have chosen to place a “sensor suite” on the roof of the vehicle, which has by now become a “signature” for automated driving. The high number of sensors makes ADS rather expensive (between \$50,000 and \$250,000 (Herger, 2020)). The expectation is, however, that the cost will decrease significantly with mass-production of these systems.

On the software side, machine learning (ML) and artificial intelligence (AI) are key enablers for automated driving. These algorithms, however, rely on “learning” from reality and stakeholders are currently investing large efforts on pilots on public roads to expose the algorithms to as many traffic situations as possible. Most stakeholders have also created virtual environments (simulations) and methods that enable them to expose the software to many more situations in a cost-efficient way. The ability to capture “edge cases” is seen as a major prerequisite for safe operation of AVs (Koopman and Wagner, 2017). There is no doubt that proving safety of ADS is one of the most difficult tasks (Kalra and Paddock, 2016).

Currently, most of AVs that are piloted still require a safety driver in the vehicle to warrant safety, due to a combination of ADS limitations and regulatory constraints. To eliminate the safety driver, stakeholders are considering teleoperations technology and human remote control of the vehicles if necessary. Ideally, a remote operator would be able to control and monitor several vehicles at the time, and thereby improve cost-efficiency. With this demand, several new stakeholders have emerged offering remote control technology and services (e.g., Phantom Auto, Voysys).

Automated Driving Systems Under Development

It is possible to distinguish four broad types of ADS (corresponding to Level 3 and 4) that are currently under development for use on public roads and that are expected to become mainstream within 5–10 years. In spite of the optimistic announcements made by some stakeholders a few years ago, most forecasts agree that launch of these ADS is likely to occur at the earliest in 2022/2023.

- **Automated shuttles and taxis** addressing first- and last-mile trips are expected to revolutionize passenger mobility. They are mainly piloted in urban areas, but there are also a few examples of pilots in rural settings (e.g., in Japan and Sweden). The pilots commonly involve a few vehicles and take place in well-defined areas, at low speeds and with a safety driver onboard. In 2018, both automated shuttles and taxis were commercialized for the first time; the shuttles were integrated into regular public transport in a residential area outside Stockholm (Sweden), while Waymo started offering commercial taxi services to select customers in Phoenix. Recently, a few stakeholders got permission to pilot their services without a safety driver onboard.
- **Automated goods delivery vehicles** address the first- and last-mile urban delivery, typically from a transportation hub to another hub or the final delivery destination. A few different types of such vehicles are under development including sidewalk delivery robots, automated delivery pods and automated cars. The latter are being developed by, for example, Waymo, Ford, and General Motors, and are largely similar to conventional delivery vehicles. Sidewalk delivery robots are created by, for example, Starship Technologies, Kiwi, and Amazon. Typically, they are electric, carry one parcel at the time, travel on sidewalks at speeds up to 5–10 km/h. Electric automated delivery pods are being developed by, for example, Nuro and Neolix. They are somewhat larger than delivery robots, can deliver several parcels at the time, travel at a slightly higher speed (10–20 km/h) and use both local roads and cyclist paths. Larger delivery pods are also being developed by, for example, Einride. While some of the automated delivery

vehicles are commercially deployed, they are typically operating in non-crowded, pre-mapped areas, and require remote monitoring. Also, these activities involve a limited number of vehicles.

- **Automated truck platooning on highways** has been under development for several years and is anticipated to improve efficiency of freight transport in terms of reduced fuel consumption (4% for the platoon leader, 10% for the followers) and road utilization, among others. It is a cooperative intelligent transport system (C-ITS) application that enables automated vehicles to drive close together with short inter-vehicular distances as road trains (i.e., automated vehicle platoons) via “connected braking” between trucks enabled by vehicle-to-vehicle communication. Current commercially available platooning systems are designed to operate only on multi-lane, divided, limited access highways and involve two vehicles only with a driver in each vehicle. In the future, the expectation is that the platoon size will be increased and that only the first vehicle in the platoon will require a human driver. Key stakeholders in the area include Volvo, MAN, Scania, Peloton, and Locomotion.
- **Automated driving on highways** is under development both for passenger and freight vehicles. Such ADS would co-exist with manual controls in vehicles and would allow human drivers to remove their hands from the steering wheel and/or under certain conditions take their eyes off from the road for longer periods of time. A key distinguishing characteristic is whether the driver must remain alert and ready to take control if the system is unable to execute the driving task (Level 3), or not (Level 4). To start with, such systems are expected to be available only under certain conditions and on certain highways.

Connected Vehicles

Connected vehicles (CV) represent the paradigm where vehicles are connected and are able to “talk” with each other, pedestrians, cyclists, and infrastructure. Technologies are multi-fold including vehicle-to-vehicle (V2V), vehicle-to-pedestrian (V2P), vehicle-to-infrastructure (V2I), and vehicle-to-network (V2N). With V2V and V2P, vehicles are able to share real-time information with each other and with vulnerable road users (VRUs) such as pedestrians and cyclists, which helps to improve situational awareness and traffic safety. With V2I and V2N, vehicles become part of the cooperative intelligent transport systems (C-ITS), where vehicles share real-time information through road and telecom infrastructure to improve traffic safety, efficiency, and comfort of traveling. Vehicle-to-everything (V2X), as a general term, covers all potential areas enabled by connected vehicles.

A Brief History of V2X

There are mainly two technology streams for V2X, the Dedicated Short Range Communications (DSRC) based on Wi-Fi technology, and the C-V2X based on cellular communications. The following part gives a brief discussion on each technology and its evolution, and the on-going debate on the technology choice.

The Path of DSRC

The research on V2X can be dated back to the 1990s when Wi-Fi based DSRC started to be tested for vehicular communications. In 1990, the US Federal Communications Commission (FCC) allocated a total of 75 MHz spectrum at the 5.9 GHz band for DSRC and adopted basic operation rules. The DSRC radio access technologies, i.e., IEEE 802.11p, are based on the IEEE 802.11a Wi-Fi standard with modifications to fit the characteristics of the vehicular communication environments. It was integrated into the IEEE 802.11 standard in 2012 and became the main physical communication specifications for vehicular communications. It is designed to support relative velocities up to 200 km/h, a communication range of up to 1000 m and a response time of around 100 ms. Based on 802.11p, major V2X standards have been built including the IEEE Wireless Access in Vehicle Environments (WAVE) in the US, the ISO Communications Access for Land Mobiles (CALM), and the EU C-ITS.

The US WAVE standards are specified in the IEEE 1609 series. They define a set of protocols, services, and interfaces for secure V2X communications. The physical communication is based on IEEE 802.11p, while the network and transport layer is based on the WAVE Short Message Protocol (WSMP). A Basic Safety Message (BSM) is defined following the SAE standard J2735, which is broadcast with a frequency around 10 Hz to improve the situational awareness. The ISO standards CALM are published through the ISO 21217 series and defines wide supports of a range of access technologies including cellular, Wireless Local Area Networks (WLAN), infrared communications, and millimeter wave communications.

In the EU C-ITS framework, the V2X standards consider both DSRC and cellular, while a significant effort has been devoted to ITS-G5, which is the EU’s DSRC technology. Similar to WAVE, ITS-G5 is based on IEEE 802.11p and works at the 5.9 GHz band, which has been in place since 2008. In 2014, the first release of C-ITS standard, that is, the C-ITS R1 was finalized and released by the EU standardization organizations CEN and ETSI (Chen and Englund, 2014). Corresponding to WSMP, the EU standards introduce the Basic Transport Protocol (BTP) and Geonetworking protocol for fast distribution of short messages with geo-location awareness. Two major messages, the Cooperative Awareness Message (CAM) and the Decentralized Environmental Notification Message (DENM) for improving the situational awareness are defined. Similar to BSM, CAM is a heartbeat single-hop message that is broadcast at a frequency of 1 Hz to 10 Hz with basic vehicle information such as location and driving dynamics. DENM is triggered by events such as road works and is broadcast at a higher frequency, for example, 10 Hz and may need multi-hop delivery to cover a geographical area. In addition, the C-ITS R1 includes a basic set of applications (BSA) that are prioritized for realistic implementations. Following the release of R1, CEN, and ETSI continues the work on the second release, which is expected to support more complex and advanced applications.

The IEEE 802.11p standard was designed 2 decades ago. To leverage the advancement of Wi-Fi technologies and to provide an evolution path for IEEE 802.11p, in 2018, the IEEE 802.11 Next Generation V2X study Group was formed and later in 2019 the IEEE 802.11bd Task Group was created. The IEEE 802.11bd represents the next generation DSRC, which aims at providing improved performance and is designed to be backward compatible and can co-exist with 802.11p.

The Rise of Cellular-Based V2X (C-V2X)

Despite that the DSRC has emerged in 1990s and enormous efforts on research and development have been investigated, the realistic implementation has been slow. The rapid evolution of cellular communications, especially the 5th generation (5G) technologies, provides another solution for V2X, that is, C-V2X. In the telecom sector, the 3rd Generation Partnership Project (3GPP) has started the V2X standardization since 3GPP Release 14 (R14), aka the 4G LTE standard. The first C-V2X standard is LTE-V2X, which was included in 3GPP R14 and supports the basic V2X applications such as those defined for DSRC. V2V direct communication is supported by extending the proximity services (ProSe) that was designed for device-to-device (D2D) communications, which was introduced in 3GPP R12. Depending on the spectrum availability, direct communications can be deployed at dedicated V2X spectrum such as the 5.9 GHz. V2I and V2N is supported through the Uu interface which is the radio interface between a mobile device and the access networks. In 2016, major players in the telecom and automotive sector created the 5G Automotive Association (5GAA), with the aim to promote C-V2X. Global connected vehicle trials based on LTE-V2X also started. In 2018, 3GPP finalized the Release 15 with enhanced range and reliability on LTE-V2X. In the meanwhile, studies on C-V2X with the 5G New Radio (NR) was also started. NR-V2X represents the future evolution of C-V2X to support advanced V2X services such as for autonomous driving. However, it needs to be mentioned that NR-V2X is not designed to be backward compatible, meaning a dual-mode of LTE-V2X and NR-V2X is needed to accommodate both the technologies.

The Technology Debate

There has been a long debate regarding the most suitable technologies for vehicular communications. For many years, DSRC has been the only choice for V2V. With multiple commercial products being tested, the technology is ready to be implemented. In 2016, the US National Highway Traffic Safety Administration (NHTSA) released rulemaking processes that would require new light vehicles to include DSRC-based V2X communications. It remains a significant rulemaking and decisions are yet to be made. Similarly in the EU, the EC adopted C-ITS rules in the form of Delegated Act (C-ITS DA) in 2019 with the aim to start large-scale implementation of C-ITS as of 2020. The C-ITS DA is built on many years tests and pilots using ITS-G5, and has received oppositions from the EU member countries that prefer a more technical neutral solution. It was suggested that DA should be technically neutral and include the C-V2X technologies. In the meanwhile, the EU C-Roads project oversees the many on going C-ITS pilots and aims at harmonizing the European C-ITS deployment. Hybrid solutions have been considered to provide C-ITS services through both DSRC and the existing 4G cellular networks. From the industry side, DSRC based V2X has been in production in Japan since 2015 and in the US since 2017 for selected vehicle models. In 2019, Volkswagen announced that its Golf 8 will be equipped with DSRC based V2X, representing one of the biggest moves from the automotive industry.

On the other hand, driven by the telematics and infotainment services, a majority of today's new cars are already connected, and a number of V2X applications can already be supported. In addition, C-V2X evolves rapidly in the latest years with multiple trials and the gradually available C-V2X chips. 5GAA has been actively working with ETSI on C-V2X interoperability test, and also with C-Roads to define C-ITS communication profiles through the 4G cellular networks and LTE-V2X. In the US, the FCC considers to reframe the 5.9 GHz spectrum to open certain spectrum for normal Wi-Fi services and to allocate 20 MHz of the V2X spectrum to C-V2X. China is moving forward on C-V2X by issuing the permit for LTE-V2X testing in 2018. Since then, multiple test sites with C-V2X have been built with involvement of major OEMs and suppliers.

Connected and Automated Driving

Along with vehicle automation and electrification, V2X is one of the keys for improved traffic safety, efficiency and contributes to sustainable transport solutions. It supports both existing vehicles and the forthcoming AVs for connected and automated driving.

The Basic V2X Applications

The basic V2X applications are mostly to improve the awareness by broadcasting simple status data or alerts. Those are for the vehicles with lower automation (Levels 0–3) where human drivers are involved and messages need to be conveyed to the drivers for action. In the C-ITS R1, the BSA are categorized into three categories including traffic safety, traffic efficiency, and cooperative local services and global internet services. Those applications were further refined into Day 1 and Day 1.5 services through the C-ITS platform in 2016 (European Commission, 2016).

Day 1 services are expected to and should be available in the short term because of their expected societal benefits and the maturity of technology. Applications include emergency electronic brake light, emergency vehicle approaching, slow or stationary vehicle(s), traffic jam ahead warning, hazardous location notification, road works warning, weather conditions, in-vehicle signage, in-vehicle speed limits, probe vehicle data, shockwave damping, Green Light Optimal Speed Advisory (GLOSA)/Time To Green (TTG), signal violation/intersection safety, and traffic signal priority request by designated vehicles.

Day 1.5 services are those that are mature and highly desired by the market, though, for which specifications or standards might not be completely ready. Those include off street parking information, on street parking information and management, park and ride information, information on fueling and charging stations, traffic information, and smart routing, zone access control for urban areas, loading zone management, VRU protection, cooperative collision risk warning, motorcycle approaching indication, and wrong way driving.

LTE supported V2X were studied in 3GPP R14 in 2015. Those services to a large extent correspond to C-ITS Day 1 services and include forward collision warning, control loss warning, emergency vehicle warning, emergency stop, cooperative adaptive cruise control, V2I emergency stop, queue warning, road safety services, automated parking system, wrong way driving warning, V2V message transfer under mobile network operator (MNO) control, pre-crash sensing warning, V2X in areas outside network coverage, V2X road safety service via infrastructure, and V2N traffic flow.

Advanced V2X Applications for Autonomous Driving

Advanced V2X applications go beyond situational awareness and are enabled by rich sensor data sharing, collective perception, and cooperative driving (Chen and Englund, 2016). Those applications can support all types of AVs especially those with higher-level automation and intelligence. The Car to Car Communication Consortium (C2C-CC) (<https://www.car-2-car.org/>) summarizes the advanced V2X application as Day 2 and Day 3+ applications. Day 2 services require improved cooperative awareness, sensor information sharing, collective perception, and improved infrastructure support. Examples of such services are overtaking warning, advanced intersection collision warning, VRU protection, motorcycle protection, cooperative adaptive cruise control (CACC), CACC string, long-term road works warning, and special vehicle prioritization. Day 3 services require, for example, trajectory/maneuver sharing, coordination/negotiation, and VRU active advertisement. Example services include advanced CACC (e.g., lane change), target driving area reservation, traffic light info optimizations with V2I, automated GLOSA, transition of control notification, improved VRU protection, cooperative merging, cooperative lane change, cooperative overtaking, CACC (string) management, cooperative transition of control and automated GLOSA with I2V negotiation.

Within 3GPP, enhancement on LTE-V2X has been published in 3GPP R15 with a list of 25 advanced V2X use cases. In 3GPP R16 (3GPP, 2018), those services were further expanded to a list of 30 use cases with addition of some general use cases. Services involving autonomous driving include enhanced V2X (eV2X) support for vehicle platooning, information exchange within platoon, automated cooperative driving for short distance grouping, information sharing for limited automated platooning, information sharing for full automated platooning, changing driving-mode, Cooperative Collision Avoidance (CoCA), information sharing for limited automated driving, information sharing for full automated driving, emergency trajectory alignment, intersection safety information provisioning for urban driving, cooperative lane change (CLC) of automated vehicles, 3D video composition for V2X scenario, automotive sensor and state map sharing, collective perception of environment, video data sharing for automated driving, QoS aspect of vehicles platooning and QoS aspects of advanced driving.

To summarize, with the advancement of both connectivity and automation, the evolution of CAV is moving towards an integrated approach. Function and service development now consider requirements on both automation and connectivity. This tight integration has led to numerous new services that are not possible with only automation or connectivity. Also, with the rapid development of artificial intelligence, CAV gradually evolves into cooperative driving where vehicles are able to coordinate locally to solve complex scenarios, that is, cooperative and automated driving.

Key Benefits, Challenges and Development Trends

The developments of AVs and CVs have followed their own paths for years; however, they are now starting to merge into an integrated path, that is, CAV. In addition, CAV also interacts closely with electric vehicles and new-shared mobility concepts, forming together major trends of future mobility. Though many benefits are emerging with CAVs, challenges remain and call for technology advancement, business development, innovation, regulatory changes as well as holistic system of system thinking and inclusive design (Fig. 2).

Key Benefits of CAV

Driven by societal challenges and opportunity for profit, large-scale introduction of AVs is anticipated to bring many benefits to the society, as discussed in the following part.

Improved safety: On lower levels of automation, some favorable impacts on safety and environment have already been proven (HLDI, 2019; Leslie et al., 2019). By eliminating driver, CAVs with higher automation levels are anticipated to improve safety even more and eliminate accidents caused by, for example, distraction, driving under influence, and speeding.

Improved transport efficiency: Lower levels of automation have small effects on transport efficiency; mostly related to reduction in accident related congestions. CAVs with higher level of automation and connectivity will be integrated into an automated transport system, which helps reducing the environmental impact by smoothing the traffic flow (Papadoulis et al., 2019).

Greater access to mobility: Regarding the growing ageing population, CAVs hold the potential to improve their access to mobility. By enabling flexible, on-demand, and driverless transport, CAVs could improve quality of life and productivity of elderly as well as people with visual impairments (Owens et al., 2019).

Figure 2 Key anticipated benefits and challenges of connected automated vehicles.

Higher productivity: With higher level of automation, those who have been commuting to work by car will become passengers and spend the commuting time doing something else. On the commercial side, transportation companies suffering from a serious driver shortage (e.g., mining, long-haul, and home delivery) will be able to operate their businesses with fewer drivers.

Reduced need for new infrastructure: By enabling vehicles to travel closer to each other, CAVs could increase highway capacity. Being able to be parked closer to each other, the usage of existing infrastructure can be improved and needs for new parking areas can be reduced.

Key Challenges and Development Trends

In view of the benefits, CAV continues its evolution in all aspects including technology advancement, transport system integration, social acceptance, and behavioral changes. Significant challenges remain and solutions to deal with those challenges will form the main development trends in the coming years (Litman, 2020).

Addressing technical limitations: Both automation and connectivity need improvement. For highly automated vehicles, continuous sensor technology advancement including new sensors, sensor fusion, positioning, and on-board computation remain challenging. Similarly, connectivity with high reliability and low latency need to tightly integrate with ADS for large scale testing and validation.

Digital and physical infrastructure: The digitalization is affecting all society functions including road infrastructure. It is clear that the CAV evolution is much faster and it is generally assumed that CAVs should be able to deal with existing roads without significant changes in the infrastructure. On the other hand, it is also agreed that close cooperation between CAVs and the infrastructure are key for a safe and efficient transport system. Incorporating physical and digital infrastructure with CAVs will form another major development trend.

General acceptance and trust: To reach anticipated benefits, CAVs will need to be trusted and gain societal acceptance. This means that CAVs need to safely, efficiently and seamlessly interact with other entities in the traffic system. The interaction between CAVs and conventional vehicles as well as vulnerable road users such as bicyclists and pedestrians remains an open research question. External vehicle interfaces (eHMI) have been proposed for such purposes (Habibovic et al., 2018; Dey et al., 2020), however, their role is yet to be explored. A growing interest in the area is foreseeable to improve the CAV acceptance and trust.

Human centric and inclusive design: The interaction between humans and technology is a central element of automated driving and remains challenging, and mobility solutions with CAVs need to be human centric and inclusive. While development of CAVs has attracted enormous research on human aspects from the driver and passenger perspective, it fails to address the special consideration of certain groups such as elderly and individuals with impairments. To ensure that CAVs and corresponding mobility services serve all people, stakeholders need to truly embrace a “whole journey” mindset using the universal design from early development phases (Habibovic et al., 2019).

New safety aspects: Early implementation of CAVs will be in environments where machine-based and human road users coexist. Considering unpredictability of such traffic situations, collisions might be inevitable in a foreseeable future. This may be addressed by traffic separation, such as proposed by NUMO with dedicated road network for CAVs (Chen et al., 2018). It may also be approached with in-depth understanding of behaviors and interactions. Both are challenging and call for research efforts. In addition, introducing CAVs may move safety issues from human-oriented to machine-oriented. These may include, for example, deficiencies in the software controlling the CAV, missing or incorrect map data or sensor data, and cyber-security challenges. It is then important to guarantee the CAV functions are safe and system malfunction are minimal. Currently, several relevant standards are under development (e.g., UL 4600, ISO 21448 SOTIF), and will go hand-in-hand with CAV evolution.

Regulations and policies: In recent years, it has become evident that the mainstream testing and adoption of CAVs requires significant policy and regulatory changes to govern design, construction, and performance of these vehicles. Governments around the world have thus developed, or are developing, regulatory frameworks and protocols for testing (and in some cases for deployment) of CAVs on public roads. The major challenge is that the rules vary widely between the countries (and states), making it difficult for manufacturers to navigate the regulatory landscape. Indeed, there are ongoing international discussions; however, changing international regulations is an extensive process that may take years, if not decades. Among the key challenges are risk assessment (i.e., how safe is safe enough?), type approval, liability, licensing, training, and insurance.

Transport system of systems: Transport system includes many stakeholders and components, where CAV and its corresponding stakeholders represent the major parties. With increasing connectivity for vehicles and infrastructure, emerging service innovation and collaboration, the transport system is transforming from a system of many silo systems into a system of systems (SoS) with closely interconnected and dependent systems. Introducing CAV in the system, may thus have a significant effect on the entire traffic system and its function in society. Regarding this, RISE and its partners have proposed NUMO, New Urban Mobility (<http://bit.ly/numo-urban-mobility>) (Chen et al., 2018), which is a fully electrified, connected, and automated transport system. Such an automated system requires holistic design and engineering with consideration of the technologies, humans, the society, and a continuous system evolution. It is therefore system of systems engineering (SoSE) is promising to assist the development and evolution of such a complex system (DeLaurentis, 2005). Since SoSE is also an emerging area, the application of SoSE for mobility with CAVs remains challenging.

Brief Conclusions

Recent decades have witnessed a rapid evolution of both automated vehicles and connected vehicles, and a gradual merge of these paths into connected automated vehicles (CAVs). These vehicles, in combination with other parallel trends such as artificial intelligence, electrification and shared economy, hold the key for a safer, more efficient, accessible, equal and inclusive mobility. This chapter presents a brief introduction of automated vehicles and connected vehicles, their current development, main enabling technologies, as well as the integration into CAVs. Due to the limited technological capability as well as various other reasons including trust, security, and difficulty to prove safety and acceptance in society and regulations, many challenges remain for fully reaching the benefits of CAV benefits. The chapter offers thus an overview of general development trends and the challenges to be solved.

The work was partly conducted within the projects System of Systems for Emergency Response and Urban Mobility funded by the Swedish Innovation Agency Vinnova and Trends and Market Analysis of Automated Driving (<https://omad.tech>) funded by RISE.

Biography

Azra Habibovic is senior researcher at RISE Research Institutes of Sweden and research area director for road-user behavior at the research center SAFER. She holds a PhD in Vehicle Safety Systems (2012) and an MSc in Electrical and Electronics Engineering (2006), both from Chalmers University of Technology, Sweden. Her research focuses on improving traffic safety and user experience by means of automation and connectivity.

Lei Chen is a senior researcher at the department of mobility and systems, RISE Research Institutes of Sweden. He holds a PhD on infra-informatics from Linköping University, Sweden and has many years' research experiences on mobile telecommunications, connected and automated vehicles and transport. His current research focuses are the application of information and communication technology (ICT) methods for improving traffic safety, efficiency, and sustainability.

Introduction

Transportation agencies regularly conduct maintenance and construction activities to preserve and rehabilitate the roadway infrastructure. These activities disrupt the normal flow of traffic on roadways and often reduce the roadway capacity, which in turn may lead to congestion and more crashes than otherwise would be expected. Transportation agencies develop work-zone traffic control plans to improve the safety of road workers and all road users and to mitigate the mobility impacts of roadwork. Work-zone traffic control aims to inform road users of the changes ahead, to guide them so that they may safely transition into the open lanes on the roadway, to ensure that road user and road workers are safely separated from each other, and then, at the end of the construction zone, to let the road users know that they have left the roadwork area.

Even though work zones occupy a relatively small fraction of a roadway system's lane miles, they are a major source of nonrecurring congestion and are considered to have higher crash rates than the parts of the roadway with no work zones. The aging of the roadway infrastructure, in countries such as the United States, means that more work zones should be expected in the next decade. Moreover, the continuous growth in the annual number of vehicle miles traveled exacerbates the safety and mobility impacts of work zones and restricts the time and locations where roadwork may be completed. This article provides a basic overview of work-zone traffic control and discusses future trends that might improve the safety of road workers and road users and mitigate the mobility impacts of roadwork. The content of this article is not intended to serve as a work-zone design and planning guide. Appropriate national and local guidelines, manuals, and standards should be followed when work zones are planned and implemented in the field.

Work-Zone Temporary Traffic Control

Work-zone temporary traffic control (TTC) aims to protect the safety of workers in the work zone while ensuring that road users move safely and efficiently through the work area. TTC encompasses seven fundamental principles that should be considered during the design phase of a roadway project and while a work zone is in place.

First, the needs of road users, including pedestrians, cyclists, and persons with disabilities, should be addressed in the work zone. The safety of road users and road workers should also be considered during the project planning, design, and construction phase, and efforts should be taken to minimize congestion because of the work zone. Second, abrupt and unnecessary changes to the travel patterns of vehicles, pedestrians, and cyclists should be avoided. Third, TTC in the work zone should be consistent with principles of positive guidance. Road users should be given adequate advanced warning about the work area and should be guided through the work zone through the use of TTC devices, such as cones and signs. Fourth, TTC devices at the work zone should be continually inspected, maintained, and modified through the life of the project. Fifth, roadside design safety should be maintained during the project, and a TTC plan should include an area for the recovery of errant vehicles. Sixth, the personnel involved in the design and implementation of the roadwork should have received appropriate training. Seventh, information related to the work zone should be communicated in advance to the public, business community, and other stakeholders (Federal Highway Administration, 2009).

Figure 1 Example of a work-zone temporary traffic control zone.

Temporary Traffic Control Zone

A work-zone TTC zone extends beyond the location where the actual roadwork is being conducted and spans to regions upstream and downstream of the roadwork area. It could also affect parallel and other nearby roads if traffic moves to them but that is not covered in this article. The TTC zone comprises four sections: (1) an advance warning area, (2) a transition area, (3) an activity area, and (4) a termination area. A segment of roadway between the first traffic control device in the advance warning area and the last work-zone-related traffic control device on the roadway is defined as the work-zone traffic control zone. **Fig. 1** illustrates an example of a work-zone TTC zone.

In the advance warning area, road users are warned of and informed about the roadwork taking place downstream. One or a series of traffic control devices is placed in this area to suggest appropriate actions that road users should take before they encounter the changes to the roadway. In the transition area, road users must adjust their travel speed and path in anticipation of downstream roadwork. Channelizing devices are often placed on this section of the roadway to create a taper and to gradually redirect the travel path of road users so that it aligns with the travel lanes at the downstream activity area. The length of the taper is determined on the basis of the speed limit of the roadway, the work-zone lane configurations (lane closure, lane shift, etc.), and the width of the lateral shift in the vehicle travel path.

The activity area, as the name implies, is the section of roadway where maintenance and construction work are taking place. The activity area is divided into three sections: (1) the work space, (2) the buffer space, and (3) the traffic space. The work space is where equipment, material, and road workers are placed and is closed to roadway users. The maintenance and construction work is conducted in this space. The buffer space is a safety feature of work zones that aims to provide an area for errant vehicles to recover. The buffer space creates a longitudinal and/or lateral empty area between the work space and the traffic space. The traffic space is the portion of the activity area reserved for use by road users. The termination area is the section of the work zone where roadway users return to their normal path.

Temporary Traffic Control Devices

This section discusses a variety of work-zone traffic control devices that may be placed on, over, or adjacent to a roadway to regulate, warn, or guide road users, including pedestrians, cyclists, and automobiles. Specific attention should be given to the

crashworthiness of the TTC devices used in work zones ([American Association of State Highway and Transportation Officials, 2011](#)). The following warning signs shapes and colors refer to US standards. Canada uses similar signs, whereas other countries typically use different shapes and colors. In most countries, text is avoided since many drivers are not familiar with the local language, whereas in the United States, it is assumed that drivers understand English.

- Work-zone warning signs in the United States typically have an orange background with a black border and a black legend (text). Warning signs are often diamond shaped and inform road users of the roadway conditions that might not be apparent to them. These signs may be supplemented with orange flags and flashing lights. Regulatory and guide signs may be used in TTC zones as well. The regulatory signs placed in work zones should be consistent with the regulatory signs placed anywhere on the roadway system.
- Portable changeable message signs may be placed on trailers or may be mounted on trucks to provide various work-zone-related information to motorists in the advance warning area. The changeable message signs can be used for speed management, for queue warning, and to direct motorists to alternate routes.
- Arrow boards warn drivers of lane closures through the use of flashing arrows, sequential arrows, or sequential chevrons, and are required on high-speed and high-volume roads. Arrow boards are referred to as “arrow panels” and may be placed on trailers or mounted on vehicles.
- Channelizing devices, such as drums, tubular markers, cones, and barricades, are placed in a work zone to guide drivers, pedestrians, and cyclists through the work zone. The retroreflectivity, height, and type of channelizing devices and the spacing between the channelizing devices are determined on the basis of the type of work zone.
- Warning lights, including flashing or steady burn lights, are used to draw the attention of drivers to channelizing devices and advance warning signs. These devices are lightweight and portable and can easily be used to supplement the retroreflectivity of work-zone traffic control devices.
- Lighting devices, such as portable light plant towers (i.e., floodlights), balloon lighting, and roadway luminaires mounted on temporary poles, are used to provide lighting in the work zone during nighttime work. The type of roadwork activity (i.e., mobile work vs. stationary work), glare (which affects road workers and road users), light trespass onto private property near the work area, and costs are the factors that determine the minimum level of lighting and the lighting method to be used.
- Delineators, high-level warning devices or flag trees, crash cushions, temporary rumble strips, temporary traffic control signals, automated flagger assistance devices, and screens are other traffic control devices used in work zones.

Work-Zone Classification

This section discusses the work-zone duration and work-zone lane configurations, which are key factors in the development of work-zone traffic control plans.

Work-Zone Lane Configuration

The work-zone lane configuration describes if (and how) road users need to adjust their travel path to travel through the work-zone activity area. The work-zone lane configuration is sometimes referred to as the “taper type” and is broadly classified into one of the following five categories:

- Lane closure(s): One or more lanes of the roadway are closed, and vehicles must merge to an adjacent open lane. Late merge and early merge are two strategies that aim to improve mobility at work zones by encouraging early or late merges in the work zone.
- Shifting lane(s): There is no lane closure, and the number of travel lanes is not reduced; however, travel lanes are laterally shifted and often narrowed.
- Shoulder work: There is no lane reduction or lane shift, and only the shoulder is closed to traffic.
- One-lane, two-way: When a lane of a two-lane, two-way road is closed, the opposing traffic movements take turns using the available open lane and the roadway turns into an alternating one-way road.
- Rolling roadblock: This type of roadwork involves slowing down or pacing traffic with the help of shadow vehicles and law enforcement to clear an entire section of roadway for a short period. The roadwork is completed in the short period that the roadway is closed and is empty of vehicles. There is no taper in the TTC plan for a rolling roadblock.

Work-Zone Duration

The duration of a work zone determines the type of TTC devices that will be used in the work zone and is taken into account in the scheduling of the roadwork. The duration of a work zone is classified into one of the following five categories:

- A mobile work zone refers to a zone where roadwork activity moves continuously or intermittently. Roadway workers may be on foot or in a vehicle; however, they rarely stop at one location for more than few minutes. Examples of this type of roadwork include roadway striping and storm drain cleaning. As the work area is constantly moving, it is desirable to utilize traffic control devices with minimal setup and removal times for work-zone traffic control.

- Short-duration work refers to stationary roadwork that can be completed in up to 1 h. Surveying and removing graffiti from roadway signs are examples of this type of roadwork.
- Short-term stationary work refers to activities that need more than 1 h but that can be completed during daylight on a single day. Examples of this type of work include structure inspections and utility work.
- Intermediate-term stationary work refers to a type of roadwork that is completed during daylight in 1–3 days. Nighttime work that is completed in more than 1 h is considered intermediate-term stationary work as well.
- Long-term stationary work refers to work that is completed in more than 3 days.

There are trade-offs between the amount of time that roadway workers spend setting up the TTC devices and the time needed to complete the work. As the roadway workers are exposed while they are setting up the TTC devices, ideally, the amount of time spent on placing the TTC devices should not be longer than the time needed to complete the actual work. For this reason, traffic control devices that are easy to set up and remove are often used in short-duration work.

The duration of roadwork is considered in traffic impact assessments and during the scheduling of roadwork. While mobile work and short-duration work are often conducted during off-peak periods, a detailed traffic impact assessment is required for stationary work zones.

Other Considerations

The majority of work zones are planned in advance, where the planning activities consider the safety and mobility impacts of the roadwork. However, events such as utility failure and localized pavement damage may require immediate and urgent repairs. Unanticipated and emergency work presents unique challenges to the road crew, as they must set up traffic control while the emergency work is being addressed. Other factors that are considered in work-zone planning include daytime versus nighttime work, roadwork in rural versus urban areas, and work zones on high-speed facilities versus local roads.

Work-Zone Safety and Mobility Impact Assessment

Transportation agencies have traditionally conducted work-zone impact assessments to determine the impact of roadwork on mobility performance measures, such as delay and the length of queues in work zones. However, in recent years the safety of road users and roadway workers in work zones has become the primary concern of transportation agencies. This section discusses practices for work-zone safety and mobility impact assessments.

Work-Zone Safety Assessment

In the current state of practice, nominal safety is upheld in the work-zone traffic control. Nominal safety indicates that all the required guidelines and standards are met when a work-zone traffic control plan is planned and implemented on the roadway. An acceptable safety of road users and workers in the work zone is ensured by adopting a multifaceted approach of engineering, education, and enforcement (3E) toward work-zone safety.

Engineering procedures and standards are followed during the planning, design, and implementation phases of a work zone. Every aspect of work-zone TTC—from the size and placement of signs in the work zone to the work-zone speed limit—is determined to ensure that minimum safety standards are met. The *Manual on Uniform Traffic Control Devices* ([Federal Highway Administration, 2009](#)) is an example of such a standard.

In addition to the mandatory aspects of work-zone traffic control required by design standards, innovative concepts, such as variable speed limits, speed warning displays, photo-enforced speed compliance, and nighttime flashing arrows, are implemented in work zones to improve work-zone safety. During the planning phase for a work zone, mobility performance measures, such as the operating speed of the work zone and the length of queue, are determined and their potential impacts on roadway safety are investigated. For example, advance warning signs are placed on the roadway to make sure that drivers are notified of a work zone before they arrive at slow-moving traffic.

Enforcement is another strategy that transportation agencies utilize to improve roadway safety at work zones. Law enforcement officers enforce speeding, no passing, and cell phone use and distracted driving laws at work zones, as these behaviors endanger the safety of the road workers and other road users. To further deter the road users from unsafe behavior, some jurisdictions have doubled the fines incurred for traffic violations at work zones in comparison to those incurred under normal roadway conditions. Considering the potential severe injuries of roadway workers as a result of roadway crashes, some jurisdictions punish drivers who hit roadway workers with prison sentences. As the presence of law enforcement at work zones is not always practical, automated speed enforcement cameras are used in some jurisdictions to enforce speed limit in work zones.

Work-zone education and awareness campaigns are another category of activities that transportation agencies use to increase public awareness of roadway worker safety and to prevent distracted driving in work zones. These campaigns are often implemented a few weeks before the construction season begins. Dynamic message signs are also used to educate road users about work-zone safety. However, limited information on the impacts of these efforts on changing driver behavior in work zones is available.

Despite the efforts of transportation agencies to provide nominal safety in work zones, crashes continue to occur in work zones because of environmental factors, driver behavior, etc ([Campbell et al., 2012](#)). Thus, it is important to understand the expected safety

performance of a work zone. This is referred to as “substantive safety.” Over the past few decades, the importance of substantive safety has been recognized by practitioners, and safety performance functions (SPFs) and crash modification factors (CMFs) have been developed as part of methodologies to predict and assess the expected safety performance of various roadway facilities. An SPF predicts the number of crashes expected at a transportation facility that meets the base geometric design and traffic conditions. For example, the base conditions for a rural multilane divided highway segment may be lanes that are 3.6 m wide, a right shoulder that is 2 m wide and paved, a median that is 10 m wide, and no lighting and no automated speed enforcement on the roadway segment. When the condition of a transportation facility differs from the base SPF conditions, CMFs are used to adjust the SPF predictions for the base condition to the actual or proposed conditions. For instance, a CMF might be used to determine the impact of a reduction of the lane width from 2 to 1.8 m.

CMFs can be utilized to determine the impact of a work zone on roadway safety. However, only a handful of CMFs have been developed for work zones. The only work-zone-related CMF in the *Highway Safety Manual* determines the number of work-zone-related crashes on the basis of the length and duration of a work zone ([American Association of State Highway and Transportation Officials, 2010](#)). Ideally, work-zone CMFs should be developed to predict the frequency, severity, and type of crashes in the advance warning area, transition area, work area, and termination area of a work zone. This information informs designers to implement appropriate countermeasures to address the safety risks.

Similarly, there is a need for the development of CMFs for a variety of work-zone traffic control strategies. For example, what is the impact of queue warning systems on reducing the number of crashes across the work zone? Developing CMFs for work-zone traffic control devices will assist engineers with the implementation of strategies that are expected to be most effective in improving the safety of work zones.

The lack of work-zone-related CMFs is in part attributed to a lack of high-resolution crash data and work-zone record management systems. The importance of a systematic archive of work-zone data was recently recognized in the industry. For example, the US Department of Transportation recently published specifications for the Work-Zone Data Exchange, which aims to standardize data collection at work zones. This effort is important, as the collection of this information will assist safety engineers with determining the factors contributing to work-zone crashes, which in turn will lead to the adoption of strategies to mitigate such crashes.

Even if the United States still does not have good data, such data exist in other countries, for example in Sweden. The Swedish Transport Administration’s Publication 2014:128 shows an analysis of all fatal roadway crashes related to roadway construction for the 11-year period, 2003–13. There were a total of 51 fatal crashes with 56 people dying in that period. A total of 12 victims were women and 44 were men. Their average age was 50 but the age of the deceased varied from 3 to 93. Out of the 56 killed, 6 were construction workers and the other 50 were road users. This means that the overall construction-zone fatality rate, including construction workers, was 0.05 per 100,000 people and year. This can be compared to the overall roadway fatality rate in Sweden for those years of 4.2 per 100,000 people or in the United States of 12.5 per 100,000 people as an average of 2003–13. So, in Sweden, 56 people died in construction zones which is 1.3% of all 4251 traffic fatalities for those years, which is not an insignificant portion, especially since another 3000 construction-zone crashes caused injuries during these years. Out of the 51 fatal crashes in the 11-year period, 15 were single-vehicle and 12 were of rear-end type. Out of the 12 rear-end crashes, the killed person was rear-ended by someone else in 5 cases and rear-ended someone else in 7 cases. Ten fatal crashes were of opposing direction type and one was an intersection fatality. Five were pedestrians hit by motor vehicles, three were bicyclists hit by motor vehicles, one was a moped rider, and two were single-bicycle crashes. Then there was one bicycle–bicycle fatal crash and one crash involving a tractor.

Almost all the fatal crashes occurred in daylight, in good weather, on high-volume roads. That those happened in daylight is not surprising since most construction work in a country this far north is done during the months when the sun is up from well before the morning commute to well after typical evening commute. Two-thirds of the fatal crashes happened in long-term, stationary work zones, 17% in rolling or moving work zones, and 10% in intermittent work zones. A majority (34 of 51) of the fatal crashes occurred within the work zone itself but most of the rear-end fatalities happened in the zone leading up to the work zone and typically after people had passed warning signs. In almost all crashes, too high speed was a contributing factor. Of the six construction workers killed, five were killed in rolling or short-term construction areas. In total, 20 people were killed in automobiles, 9 on motorcycles, 8 in trucks, 6 on bicycles, 5 as pedestrians, 2 in construction-work vehicles, and 1 person on a moped. Of the six construction workers killed, one was traveling in a passenger car, two in construction vehicles, two in trucks, and one was not inside a vehicle and is therefore classified as a pedestrian. The primary object struck was in 24 cases a vehicle in motion, in 9 cases a stopped vehicle, in 11 cases the ground, and in 7 cases a barrier or bridge abutment. In at least six of the crashes, a person was under the influence of alcohol or drugs.

A total of 17 fatal crashes occurred on rural two-lane roads, 12 on multilane motorways (freeways), 3 on two-lane limited access highways (with one lane in each direction), 2 on rural multilane roads (more than two lanes), 5 on “narrow” rural roads (lacking centerline), 5 on two-lane urban streets, 1 on a four-lane urban street, and 3 at unclassified segments.

More than half of these Swedish fatal crashes occurred on roads that normally have a speed limit of 90 km/h (56 mph) or higher. The speed limit had been temporarily reduced in at least 19 of the 51 fatal crashes. For 18 of the fatal crashes, nominal safety was met with all signage following the protocol perfectly and, for 4 of the crashes, signage was done incorrectly. In the remaining 29 crashes, it is unclear whether plans had been followed.

Work-Zone Mobility Impact Assessment

Although motorists understand that work zones negatively affect mobility, transportation agencies conduct work-zone traffic impact assessments to ensure that delays and queues at work zones do not exceed acceptable thresholds. In general, work-zone traffic impact

assessment techniques can be classified into two broad categories: analytical methods and traffic simulation models. Analytical methods employ queuing theory and parametric and nonparametric models to estimate work-zone performance measures. These methods are coded into custom spreadsheets or are developed as stand-alone work-zone-specific analytical tools. The work-zone hourly traffic volume, work-zone lane configuration, and work-zone capacity are among the most common input parameters of these tools. Delay, length of queue, and costs to road users are among the output parameters of these models.

Traffic simulation models, on the other hand, are often computationally intensive and require more effort to code the work zone. However, a simulation model provides a detailed analysis of the impact of a work zone on corridor mobility and traffic operations at upstream on-ramps, off-ramps, and detour routes. A traffic simulation model also allows the study of complex and nonconventional work-zone configurations. However, the results of simulation models are meaningful only when the simulation model is calibrated to replicate the work-zone capacity.

Worker Safety

Even though transportation agencies attempt to guide drivers through work zones safely, errant vehicles occasionally intrude the taper and work area, which puts road workers at grave risk. Work-zone intrusion alarm systems have been developed to warn road workers about immediate hazardous conditions. These alarm systems utilize various sensor technologies to detect impacts with work-zone traffic control devices or use radar, Light Detection and Ranging (LiDAR), or other similar systems to monitor the taper, buffer space, and work area and to detect a vehicle intrusion. Workers are then warned about the intrusion through visual, audio, and/or haptic warnings. Another strategy used to protect roadway workers and errant vehicle occupants are truck-mounted attenuators (TMAs), which will be discussed in the next section.

Truck-Mounted Attenuators

Protective vehicles are placed in work zones to shield road workers from errant vehicles and to improve the safety of travelers. The protective vehicles include advance warning vehicles, barrier vehicles, and shadow vehicles. Advance warning vehicles are equipped with an arrow board to inform drivers about the downstream roadwork and are typically placed on the shoulder in the work-zone advance warning area. Barrier vehicles and shadow vehicles are placed in the activity area to protect road workers from errant vehicles and to protect errant vehicles from an impact with construction equipment. Barrier vehicles are typically used in stationary roadwork and are not occupied by drivers. Shadow vehicles, on the other hand, are used in mobile operations.

TMAs are attached to protective vehicles to reduce the risk of injury to the passengers of a vehicle that crashes head-on into the protective vehicle. **Fig. 2** illustrates examples of TMAs. TMAs function as a portable crash cushion that is attached to the rear of a truck and are designed to absorb a portion of the crash impact energy. There are two primary considerations with regard to choosing a TMA for a work zone.

The first factor is the level of crash protection provided by the TMA. The commercially available TMAs provide either Test Level (TL) II or TL III, as defined in *NCHRP Report 350: Recommended Procedures for the Safety Performance Evaluation of Highway Features* (Ross et al., 1993). TL II TMAs are designed to absorb some of the impacts of a crash when the difference between the speed of the TMA and the speed of the vehicle crashing into the TMA is 70 km/h, whereas TL III TMAs are designed to accommodate a speed differential of up to 100 km/h. Although TMAs are often designed to provide protection against rear-end crashes, some TMAs provide protection against angle collisions as well.

The second factor is the weight and type of vehicle to which the TMA is attached. Attaching the TMA to lightweight vehicles may provide protection against errant passenger cars; however, attaching the TMA to heavy vehicles reduces the risk that the protective vehicle will be pushed into the work space if a tractor trailer hits the TMA at a high speed. Manufacturer guidelines and

Figure 2 TMAs utilized by the Missouri and Oregon Departments of Transportation.

transportation agency manuals determine the appropriate type of TMA for a work zone and the type of vehicle to which a TMA should be connected.

When a TMA is struck by an errant vehicle, it is very likely that the TMA will be pushed forward as the result of the impact. The distance that the TMA is pushed forward is referred to as the “roll-ahead distance.” The roll-ahead distance is a function of the weight of the TMA, the weight of the errant vehicle, and the speed of impact. It is important that the roll-ahead area in front of a TMA be free of roadway equipment and road workers.

In addition, TMAs extend behind the vehicle to which they are attached, and it is essential to ensure that TMAs are highly visible to drivers, particularly during nighttime. Retroreflective materials and warning lights may be used to improve the visibility of TMAs.

In addition to TMAs that are attached to trucks, trailer-mounted TMAs are also available. The advantage of these TMAs is that the vehicles can be removed from the TMA at the work site so that the driver and the vehicle are free for other activities.

Finally, when a TMA is struck, the driver of the TMA is at risk of injury as a result of the impact. To address this situation, transportation agencies have recently experimented with semiautonomous TMAs, where a driverless TMA follows a lead vehicle so that the TMA is no longer occupied by a driver.

Future Trends in Work Zones

A key requirement for improving safety and mobility in work zones is access to high-resolution archival work-zone data. Examples of these data include detailed work activity diaries, traffic data collected at the taper and upstream of the taper, work-zone lane-configuration record, and crash records that identify the location of crashes with respect to work-zone traffic control zone areas. These high-resolution data are typically not collected at work zones, and, when collected, they are collected and stored in an arbitrary manner. The Work-Zone Activity Data (WZAD) protocol currently under development aims to improve the quality and the consistency of US data collected and the timeliness of data collection at work zones and will serve as a standard for data collection at work zones.

Another area where WZAD may be useful is mitigating the challenges associated with the travel of connected and autonomous vehicles (CAVs) through work zones. Work zones create irregularities in the road, and CAVs need to accurately process the information provided in the TTC zone to navigate the work zone safely. The accurately processing this information is challenging, as work zones and activity types vary greatly, and there is always the risk that TTC devices may be damaged or not updated to reflect changes in the work area. CAVs could receive the work-zone layout in the advance warning area through vehicle-to-infrastructure communication, communicate with the traffic control devices in the work zones to prevent work-zone intrusions, reduce the delay and the length of queue in work zones through the use of cooperation and lane changes, and issue electronic warnings to roadway workers when a potential crash is predicted. In the long term, CAVs are expected to improve safety and mobility in work zones.

The economic costs of accidents are a result of lost scarce resources. There are three types of economic costs: material costs, medical costs, and the value of lost production. Material costs are lost resources due to damaged vehicles, destroyed materials, time for repairs and time for police and for administration of insurances. Medical costs are lost resources in the health care sector, including time for physicians and nurses, use of medical devices, and time for caregivers. These are examples of costs related to fatal and nonfatal casualties. Material costs and health care costs are direct costs. The third type of cost is the value of lost production, due to sick leave, early retirement, and premature death. These costs are called indirect costs.

Costs of accidents can be considered from a broad societal perspective, that is, including all consequences independent of who is taken the burden of the costs. Estimates of costs from a broad societal perspective, that is the socioeconomic accident costs, can be of interest for various purposes. One of the purposes is the evaluation of the benefits of road safety measures. Cost offsets from preventing accidents are a value driver for traffic measures. Another purpose is the ex post representation of the extent of consequences in monetary terms to illustrate the burden of injuries, and compare this with such other costs, as for instance, costs for other types of injuries or diseases. A third purpose of costing is to estimate the external costs of road accidents in order to internalize various economic costs to influence road user behavior. A fourth purpose is to use estimates as a basis for judicial assessments of the sums paid in compensation for damages and other lost resources.

Estimation of accident costs involves identifying, measuring, and valuing all resources lost that occur as a result of the accidents. Valuing resources lost often rely on market prices as far as they are available. For material damage costs and administrative costs, there are usually market prices. For personal injuries there are market prices available; however, different methods must be used for direct and indirect personal casualties.

Direct health care costs are mainly based on market prices taken from the estimates of expenditures for health care and social services for home care. Indirect costs are mainly valued by the human-capital approach. Under this approach, the estimation of lost output is normally based on the wages that could have been earned by individuals if the illness or injury in question had not happened. The methodology was early applied in the 17th century by Sir William Petty (1699). Another contribution to the literature is "The Money value of a Man" by Dublin and Lotka (1946). Their purpose was to "estimate the value of a man to his dependents, that is to those who have a direct interest in his earnings." In answering this question, Dublin and Lotka estimated the discounted present value of an individual's net earnings. The net earnings were defined as the difference between discounted present value of future earnings and future consumption expenditures. It is also an answer to the question: "What is the size of a life insurance for an individual in order to guarantee the same material living standard to a family should the family provider die?" This net value is also comparable to the value of a slave on the slave market, that is, the expected value of a slave's production minus the costs to give the slave food and shelter. One of the first traffic accident cost estimations was applications with this methodology. For example, Dawson (1967) estimated the costs in Great Britain.

With this net value approach, or slave calculations, the sick or injured person's value of own consumption loss is not included. Another approach including the sick or injured individuals' consumption is the gross loss of production value. In these calculations there is no reduction of consumption value. The classical use of this approach is the estimate of the cost of war (Petty, 1964). The costs of the French–German war in 1870–71 were estimated by Giffen (1880). The US involvement in the First World War and the associated loss of human resources valued by using the value of gross lost production was estimated by Clark (1931). This is the same approach that later on have been used to estimate the value of lost production due to illness and injuries in the cost of illness studies (COI).

The seminal work in the field of COI is Dorothy P Rice's study of 1966, which presents and applies a methodology for estimating the cost of major disease categories in the United States (Rice, 1966). Additional examples of application for Sweden were Lindgren (1981), Rydenfelt (1949), and Rydenfelt (1991).

Under this approach, the economic costs associated with diseases or injuries are divided into two principle categories: direct costs and indirect costs. Direct costs represent the value of resources used for prevention, detection, treatment, rehabilitation, and long-term care due to the existence of illness or injuries. Costs are estimated by summing up the expenditures on each category attributable to the disease or injury of interest. Indirect costs represent the value of the goods and services that would have been produced if a person had not fallen ill or been injured. Often this is estimated using the "human capital" approach, whereby the lost output is

measured by the wages that could have been earned by individuals if the illness or injury in question had not happened. To estimate costs, observed market prices of goods, services, and the labor force are used.

The traffic accident costs in Sweden was published by Mattsson (1970). Hartunian et al. (1981) published the economic costs of the annual incidence of coronary heart disease, cerebrovascular disease, cancer, and motor vehicle injuries in the US 1975. Krupp and Hundhausen (1984) estimated the costs of road traffic accidents in Germany, and Jensen (1983) and Elvik (1989) the costs in Denmark and Norway, respectively. Apart from the study by Hartunian et al. (1981) there are also other US estimates (Rice et al., 1989). One international comparison of socio-economic accident costs was the project COST 313—Socioeconomic cost of road accidents (Alfaro et al., 1994). This project attempted to show how costs of accidents could be evaluated and how different methods and differences in terms of application affect the outcome.

Incidence and Prevalence

Estimates of health-care costs and value for lost production are commonly conducted using the prevalence approach, that is, the health care costs and the value of lost production during a certain time-period caused by a given injury are estimated, irrespective of when the injury emerged. However, traffic accidents often lead to costs that arise 5–10 years after the accident. By using the incidence approach, all present and future health care costs are estimated and discounted to the year in question. This approach is more commonly used when analyzing preventive programs or programs aimed at rehabilitation (Hartunian et al., 1981). Fig. 1 illustrates the difference between the two approaches.

For injuries causing short-term consequences, that is, consequences with durations shorter than one year, there is no difference between the incidence and the prevalence approach. However, for injuries resulting in long-term consequences, the two approaches will have different results even in a steady state situation, that is where the number of accidents, severity of accidents, and costs per accident are constant over time. The reason for this is that under the prevalence approach no costs will be discounted but under the incidence approach all future costs will be discounted. The present value for incidence approached costs will therefore always result in less aggregate costs than prevalence-based cost calculations.

Cost estimates under the prevalence approach are often not a “pure” application of the theoretical correct prevalence approach. In practice, there are two exceptions that have to do with the calculations of indirect costs due to premature death and early retirement. The indirect costs due to premature death and early retirement used to be estimated from the time of the accident and for subsequent time periods until the individuals are expected to die or not produce any productive work anymore, respectively. In other

Figure 1 (A) and (B): consequences to include for estimating the material costs of accidents with the incidence and the prevalence approach, respectively. (A) Costs for consequences that should be included then estimating cost of accidents for year 2 with the incidence approach (shaded areas). (B) Costs for consequences that should be included then estimating cost of accidents for year 2 with the prevalence approach (shaded areas). Source: Own figure.

words, a usual technique for the prevalence approach is to apply a similar procedure for estimating these costs as for estimating them with the incidence approach, that is, discount future indirect costs.

The explanation for this procedure is that a pure application of the prevalence approach even for mortality and early retirement includes both data collection problems and conceptual difficulties in interpreting the results. For example, a pure prevalence application requires information about the number of individuals that should have been alive and productive during the year in question, if accidents had not happened at any year prior to the year in question. In order to avoid the problem of constructing a hypothetical model on which basis a counterfactual situation can be deducted, researchers apply the prevalence approach by making these two exceptions.

Both the prevalence and the incidence approach are theoretically correct, but results will differ for all discount rates above zero. The two approaches will be used to answer two different questions. The prevalence approach will answer the question: what is the economic burden of injuries for one year regardless of when they occurred? This is a question relevant for those interested in allocating resources to the health care sector treating injured persons during a certain budget year. The incidence approach will answer the question: what is the cost offset by reducing the number of accidents the forthcoming year? This is a question of interest for those allocating resources to accident prevention and to estimate the relationship between investments in traffic safety measures and the benefits of future costs savings.

For those interested in creating incentives for drivers to take account of economic consequences by internalizing accidents costs, for example, in motor vehicle insurance (Skogh and Katz, 2002), the incidence approach is also the most relevant approach. For creating fees for private vehicle insurances corresponding to accident costs, it is important to understand the amount of future economic burden and identify the most important cost components, the incidence approach, and applications for traffic injuries will be needed.

Data Requirements for Incidence Cost Studies

Accidents lead to healthcare costs and lost production during a certain time-period, for example the year when the injury occurred. However, accidents may also lead to costs that arise many years after the accident. By using the incidence approach, all present and future health care costs are estimated and discounted to the year in question.

Long-term follow-up of patient cohorts with severe casualties, registering overall survival and health care consumption are required for estimating health care costs in economic evaluation of preventive measures. This approach is commonly more difficult to apply than the prevalence approach due to less relevant data from cohorts available.

Two examples of studies have been used for incidence estimates of traffic accident costs in Sweden and these are used here as examples. The first Swedish study on long-term consequences due to traffic injuries were conducted by Thorsson (1975). In Thorson's study, individuals injured in road traffic accidents during the middle of the 1960s participated in a long-term medical follow-up. Investigators interviewed and examined the injured 4–5 years after the accident. The follow-up showed that more than half of the injured suffered from some sort of aftereffect of the original injury 4–5 years after the accident. The Thorson's study provides information of the long-term consequences in terms of loss of health, and this information was used for estimating cost of care (Persson, 1982).

The second study by Persson et al. (2004) collected data on resource consumption for care for 95 severe traffic casualties due to road traffic accidents occurring in a 12-month period, 1991/1992, in Sweden and over a subsequent period of 8 years. The study also brings to light the extent of employment 8 years after the accident, an important outcome of rehabilitation for individuals injured in traffic. The Persson et al.'s (2004) study shows that 2/3 of the costs arise during the period 2–8 years after the accident. More than half of the total costs consist of lost production. Moreover, the individuals themselves are affected due to loss of income. The total costs of in-patient care arise during the first year after the accident. The costs of outpatient care and cost of care at home care are fairly equally divided by the first year after the accident and the following 2–8 years.

Of the 75 injured people who were considered to be part of the labor market, one-third did not return completely to work. The majority of those who did not return completely to the labor market were women. The total costs of production losses amount to be a major part of the total costs of traffic injuries.

Because 2/3 of the costs appear 2–8 years after the accident and these are the costs that are hard to capture with conventional registrations of care cost data, specific cohort studies are needed. Capturing information of costs of home care, special forms of housing and lost production require many years follow-up after the accident.

A general problem with such long-term follow-up studies as 8 years is the risk of including cost of health care and social services that are related to increasing age, and therefore including costs that would have appeared even in the absence of a traffic accident. The data collection in the study by Persson et al. (2004) is mainly based on the subjects' own judgment of which services to include. As most subjects belongs to younger age groups, it was expected that comorbidity, that is individuals suffering from injuries and other diseases at the same time, and age-related costs might be a minor problem when studying accidents with this method. For many other types of injuries and sicknesses, particularly among elderly, long-term follow-up studies could be heavily biased by comorbidity and age-related costs.

Cost Offsets and Values of Risk Reduction

When seeking answer to the question: what is the value of reducing physical risk and reducing fatalities and nonfatal casualties? To answer this question an estimate of the cost offsets from material costs, medical costs and lost production is needed. In addition, the

value of risk reduction per se is also relevant. The value of risk reduction per se is a measure of how much society is willing to pay (WTP) in addition to the summary of health care costs, gross lost production, cost of property damage, and administration for improved traffic safety. In some countries, for example Sweden, this was earlier denoted "the human value." However, it is nowadays customary to denote the WTP estimate the value of risk reduction per se.

This value will not be discussed further here, but there is a potential risk of double counting when estimating the value of risk reduction when adding the value of risk reduction based on studies trading of income for risk to the material costs discussed here.

For example, the Swedish National Road Administration, when estimating the value of reducing the risk of one statistical fatality, assumes that individuals when answering the question of the value of risk reduction per se also include the value of lost consumption. If so the individual's value of lost consumption should be withdrawn from the total value of a statistical fatality.

Furthermore, if so, the estimate of the value of risk reduction corresponding to one statistical fatal casualty the risk reduction per se should be added to the net lost production, that is gross lost production minus consumption. This is the slave calculation, and this is the relevant material cost that should be added to the value of risk reduction per se, that is, the WTP amount estimated from stated preferences or revealed preferences.

For nonfatal casualties, without any risk of death, the risk of double counting is less and the value of consumption should not be withdrawn. The methods of contingent valuation and revealed preference, answer the question of value of safety for the individual herself and the estimates include their preferences for risk, that is risk aversion, and these methods are discussed elsewhere.

Biography

Ulf Persson, PhD, is Former Adjunct Professor at the Institute for Economic Research, Lund University, Researcher in transport economics at the Department of Technology and Society, Lund Institute of Technology, Lund University, CEO and Research Director at the Swedish Institute for Health Economics (IHE). Now he is Senior Advisor at IHE. He has 39 years research experience in the development and application of economic evaluation methods in health care. His main research areas are health economics and transport economics. He has published 260 articles, books, and reports in health economics and economics of transport safety.

Introduction

Large trucks are the primary means of transporting cargo on roadways. Large trucks include tractors or lorries that can be paired with one or several trailers, non-articulated straight trucks, dump trucks, refuse trucks, and cement trucks. By US definition, large trucks weigh more than 26,000 lb, which equals 11,800 kg; however, a tractor with a fully loaded trailer can weigh as much as 80,000 lb (36,300 kg) or more. In many US states, an oversize permit is required for weights above 80,000 lb, whereas other US states allow heavier trucks on certain roads without a special permit. For example, Maine, New Hampshire, and Vermont allow trucks with weights up to 100,000 lb (45,400 kg) on all state roads, freeways, and interstate roads. Alaska allows the heaviest vehicle truck combinations of up to 138,000 lb (62,600 kg) without needing overweight permits. In other countries, even heavier trucks are allowed. For example, since 2015, 64 metric ton (141,000 lb) trucks are allowed on all roads in Sweden, although urban areas may restrict vehicle length and thereby gross weight. Before 2015, “only” 60 metric ton (132,000 lb) trucks were allowed in Sweden. Furthermore, in Sweden and Finland, 74 metric ton (163,000 lb) trucks are allowed on approved roads since 2018. In several other EU countries, only 40 metric ton (88,000 lb) combinations are allowed. The heaviest vehicle combinations allowed on public roads anywhere in the world, without special permit, are the Australian so-called road trains, weighing up to 200 metric tons (440,000 lb). However, these road trains are allowed only on approved roads. Thus, dependent on jurisdiction, fully loaded large trucks may be 20–200 times heavier than typical passenger vehicles.

Additionally, large trucks with trailers in the United States may, without permits, be up to 19.8 m (65 ft.) long. In Sweden, 25.25 m (82.8 ft.) trucks are allowed on all roads without special permits but city ordinances may limit lengths on urban streets. In Australia, 27.5 m (92 ft.) long combinations are allowed “everywhere” including in cities, whereas road trains that are 36.5 m (120 ft.) are only permitted to travel on approved routes. This means that large trucks can be much longer than the average passenger vehicle.

Due to the mass and length of these vehicles, large truck crashes should be disproportionately dangerous and costly. On average, large trucks account for less than 5% of the registered vehicles in the United States but are involved in more than 10% of all fatal crashes annually. But large trucks are also driven longer distances per year. In 2016, the US Federal Highway Administration (FHWA) states that Class 8 trucks (gross weights over 33,000 lb or 15,000 kg), on average, traveled 68,155 miles (109,685 km) per year, whereas passenger cars traveled only 11,244 miles (18,091 km) per year. Large truck crash involvement in Europe has similar

numbers. The large truck overall crash rate per distance driven is lower than passenger vehicle in most countries. However, large truck–passenger vehicle crashes often have more serious consequences because of large trucks’ heavier weights. Thus, in many countries the large truck fatal crash rate per distance driven is higher than passenger vehicles. For example, in 2016, passenger vehicles were involved in 1.16 fatal crashes per million miles (1.61 million km) traveled, whereas large trucks were involved in 1.29 fatal crashes per million miles (1.61 million km) traveled. This is not the case in all countries. For example, in Sweden, large trucks (defined as trucks weighing above 3500 kg or 7700 lb) are not overrepresented in fatal crashes per kilogram driven. Many other countries lack good data, but statistics suggests large truck crashes in developing countries may be deadlier due to lower standards for vehicle crashworthiness, fewer and laxer safety regulations, and higher densities of two-wheeled vehicles. And, two-wheeled riders may be disproportionately killed by heavy trucks in industrialized countries too. In 2016, 271 collisions between heavy goods vehicles (HGVs) and bicyclists in London, England, resulted in 16 riders being killed and 56 seriously injured and a further 198 injured. Although only 1.5% of cyclist casualties occurred in collisions with HGVs, this resulted in 16% of cyclist deaths. Many of them were killed by right-turning HGVs. That may also be an issue in other countries as evidenced by studies from Stockholm, Sweden. In the 5-year period 2007–11, “only” seven bicyclists were killed in the city of Stockholm, but five of the seven were killed by heavy trucks turning right at intersections.

Truck Size and Weight

In the United States, large truck size and weight restrictions are set in statute by legislation and managed by the Department of Transportation’s FHWA’s Office of Freight Management and Operations. FHWA, in coordination with the Federal Motor Carrier Safety Administration (FMCSA) and the Commercial Vehicle Safety Alliance (CVSA), oversees state enforcement of commercial motor vehicle (CMV; large truck and bus) size and weight standards in the United States. In other countries, similar agencies have similar responsibilities.

Vehicle Length

As opposed to in many other countries, in the United States, there are no federal or state overall length limits for most truck tractor-semitrailer combinations. However, the overall length of containers and trailers is regulated by federal agencies for roads that receive federal funding. In Europe, it is the bumper-to-bumper length that is regulated. This has led to very different designs of truck tractors in the United States and Europe. In the United States, the engine sticks out in front of the cab, and the cab is often long. In Europe, the engine is below the driver, and the cab is very short.

In the United States, combination vehicles (i.e., truck tractor plus semitrailer or trailer) specifically designed to carry automobiles or boats may not exceed a maximum overall vehicle length of 65 or 75 ft. (19.81 or 22.86 m), depending on the type of connection between the tractor and trailer. No state may impose a length limitation of less than 48 ft. (14.63 m) on a semitrailer (single) or less than 28 ft. (8.53 m) on a semitrailer (twin-trailer) operating in any truck tractor-semitrailer combination under federal regulations. In Europe, countries regulate the maximum length of trucks, and the maximum length varies from country to country.

Vehicle Width

In the United States, no state may impose a width limitation of less than 102 in. which is 2.59 m. That is also the widest truck allowed on most US roads without a special permit except in Hawaii where trucks can be 108 in. (2.74 m) wide. Safety devices, such as mirrors and handholds, are not included in the calculation of width. In Sweden, the maximum allowed width is 2.60 m, again allowing safety devices to extend beyond that width. In some other EU countries, vehicles are not allowed to be wider than 2.55 m without special permits.

Vehicle Height

US State standards range from 4.11 to 4.57 m (13.6–15 ft.). No US federal vehicle height limit exists. In Sweden, the clearance has to be signed if it is less than 4.5 m (14.75 ft.), so that is the de facto allowed maximum vehicle height. In other European countries, only 4.0 m (13.1 ft.) vehicles are allowed.

Vehicle Weight

Federal CMV maximum standards on the interstate highway system and highways are 20,000 lb (9,000 kg) for single axle, 34,000 lb (15,400 kg) for tandem axle, and limit maximum gross vehicle weight to 80,000 lb (36,300 kg). Additionally, the FHWA regulates the weight distribution per axle as shown in [Fig. 1](#). In 1975, FHWA introduced the bridge formula to reduce the risk of damage to highway bridges by requiring more axles, or a longer wheelbase, to compensate for increased vehicle weight. The formula may require a lower gross vehicle weight, depending on the number and spacing of the axles in the combination vehicle.

The research on oversized and overweight loads suggests that these trucks do significantly more damage to highway infrastructure, such as pavements and bridges ([Luskin and Walton, 2001](#)). Many bridges were not built to handle higher weights and should be strengthened to withstand heavier truck and trailer weights. Additionally, oversized and overweight trucks are harder to steer and control and may be at higher risk of a serious crash.

Figure 1 Commercial motor vehicle weight distribution.

Figure 2 Crash causation pyramid.

Truck Crash Causation

Decades of research have consistently found driver behaviors to be the primary contributory factors in approximately 90% of large truck crashes, just like driver behavior contributes to at least 90% of passenger car crashes ([Federal Motor Carrier Safety Administration, 2006](#)). These driver behaviors include purposeful risky driving, such as driving faster than the speed limit, traveling too fast for conditions, and tailgating. However, other driver behaviors that contribute to crashes include inattention, poor performance, inappropriate decision-making, and medical conditions. In spite of this, in multiple-vehicle collisions involving a truck and a passenger vehicle, it is more frequently the behaviors of the passenger vehicle driver, not the large truck driver, that lead to the crash.

Prior to being involved in a crash that resulted from a particular behavior leading to a crash, the driver likely performed that same error or risky behavior at least once, if not many times, before. In fact, it is likely the driver performed the risky behavior or error hundreds or thousands of times before a crash occurred. These behaviors are the leading indicators of crashes and should be the primary focus in efforts to prevent large truck crashes. Unfortunately, these leading indicators are often not measured. Instead, lagging indicators are more commonly used to measure large truck safety. Lagging indicators are reactive and are the result of unsafe performance. Examples of lagging indicators include violations, minor crashes, injury crashes, and fatal crashes ([Fig. 2](#)).

Although lagging indicators are useful in measuring the overall effectiveness of safety countermeasures, they should not be the only measure of safety or countermeasure effectiveness. Instead, research should focus on eliminating risky behaviors in order to reduce the number of near crashes, minor crashes, and serious crashes.

Risk Factors for Large Truck Crashes and Effective Strategies to Improve Safety

There are three high-level strategies to prevent large truck crashes: education, enforcement, and engineering ([Fig. 3](#)). Education countermeasures focus on educating the large truck driver and/or large truck fleets on safe driving practices and their importance. Examples of education countermeasures include commercial driver license training programs, health and wellness programs, and individual driver coaching. Enforcement countermeasures focus on providing consequences for not adhering to safety-related laws or regulations. Examples of enforcement countermeasures include roadside vehicle inspections and the enforcement of laws and regulations related to distracted driving or speeding. Engineering countermeasures use engineering principles to redesign the roadway or vehicles to reduce crashes. Common engineering countermeasures include the development of advanced driver assistance systems (ADASs), infrastructure maintenance, and improved roadway and vehicle lighting.

The following sections provide high-level overviews of risky behaviors related to large trucks, and effective education, engineering, and enforcement strategies to prevent large truck crashes.

Figure 3 Three strategies to reduce crashes.

Figure 4 Impact of safety culture.

Fleet Safety Culture

Research has long shown a connection between employees' safety performance and organizational safety culture in manufacturing and industrial environments. More recently, research confirmed the connection between large truck fleets' safety culture and their safety performance (Camden et al., 2019). Each fleet has policies and programs aimed at reducing crashes and violations. These policies and programs dictate the countermeasures used to prevent crashes. If effective, these countermeasures reduce crashes, which improve fleet safety and further reinforce the safety culture of the fleet. Conversely, insufficient policies and programs related to safety may actually encourage unsafe driving, which could lead to a fleet developing poor safety culture (Fig. 4).

Although all employees in a fleet create the safety culture, safety culture begins at the top of the organization. This includes the owner, executives, and upper management. Upper management can demonstrate their commitment to safety through regular attendance at safety meetings, frequent communications centered on safety performance, the sharing of fleet-wide safety data, providing safety leadership, and investing in safe equipment and ADAS. Although a strong safety culture begins with buy-in from upper management, driver accountability for safe driving and buy-in to the safety improvement process is critical. The most effective means to generate driver buy-in is to provide positive, supportive feedback on safe and unsafe driving habits, trust that drivers will do their best to perform their job safely, actively listen to feedback provided by drivers, and allow drivers to develop their own goals related to safety.

Steps to Develop a Strong Safety Culture

Improving fleet safety culture is a lengthy and difficult process, but with dedication and effort, it is possible. Fleets should follow a four-step process to develop a strong safety culture. First, the fleet needs to assess its current safety culture. Fleets should review current safety-related policies and programs, examine how the fleet currently measures safety, identify how safety-related messages are currently communicated, and examine barriers that create challenges to improved safety. The second step involves using the information from the first step to perform a gap analysis to identify areas in need of improvement. The outcome of this analysis will serve as the fleet's road map to improved safety. The third step is to design strategies to address all areas in need of improvement. These strategies may include developing high-level safety-related goals, creating new policies and programs to communicate about safety across the fleet, developing improved driver education/training, identifying new safety-related measures, and implementing safety-related technologies. Finally, once these strategies are developed, the fleet should implement, track, and measure their effectiveness.

Large Truck Driver Inattention

Distraction from secondary tasks, fatigue, drowsiness, impairment from drugs and alcohol, and medical conditions that cause drowsiness (such as obstructive sleep apnea and narcolepsy) are all topics under the inattention umbrella. Here we define and describe distraction from secondary tasks, fatigue and drowsiness, and impairment from drugs and alcohol.

Distraction From Secondary Tasks

Secondary tasks are nondriving tasks or, more specifically, those tasks that are not related to the safe operation of the vehicle (texting, dialing a cell phone, talking/listening on a cell phone, using a dispatching device, adjusting the radio, etc.). A common sense definition of distraction is “any task that requires the driver to take attention away from the driving task.” However, this definition is misleading, as it implies that anything that takes a driver’s attention away from the driving task is dangerous. A better definition for driver distraction is “a mismatch between the current attentional resources and those necessary to safely operate the vehicle.” This definition implies that some secondary tasks are risky and others are not, a concept supported by naturalistic truck driving research. Most prior research on driver distraction focused on passenger car drivers, with a few studies including large truck drivers. A naturalistic truck driving study focused on the prevalence and risk of secondary tasks in a sample of large truck drivers found that those secondary tasks that required the driver to take their eyes away from the forward roadway increased risk, and those secondary tasks that only required cognitive effort did not increase risk (Olson et al., 2009). Fig. 5 illustrates that the blue line is the odds ratio (the higher the odds ratio, the greater the risk) and the red line is the amount of time looking away from the forward roadway. Texting while driving a large truck increased risk by 23 times, as it was associated with driving while looking away from the forward roadway for a long time. Talking/listening on a hands-free cell phone while driving a large truck actually reduced risk, as it was associated with the driver looking at the forward roadway. Interestingly, large truck drivers performed many work tasks while driving that were considered dangerous, such as interacting with a dispatching device, writing on pad/notebook, using a calculator, and reading. Research, policy, and training and education have largely focused on nomadic electronic device use (e.g., cell phone); however, it appears that this population is also prone to multitasking that involves work-related secondary tasks. Many technologies can prevent and/or mitigate the harmful effects of distracted driving, including crash avoidance systems (e.g., automatic emergency braking, lane departure warning, side collision warning, etc.) and onboard monitoring systems.

Figure 5 Risk of commercial motor vehicle driver distraction.

Figure 6 Driver fatigue.

Driver Fatigue and Drowsiness

The terms driver fatigue and drowsiness are often used interchangeably because their consequences are relatively similar; however, their etiology is different. Drowsiness is related to sleep quantity and quality, whereas fatigue is related to the driving task. Task-related fatigue can be passive (e.g., driving for a long time) or active (heavy loading/unloading activity). **Fig. 6** illustrates these concepts and some of the factors that influence drowsiness and fatigue. Large truck driver fatigue and drowsiness can interact, compounding their impact on driver performance (e.g., limited amount of sleep and driving for a long time). Drowsiness and fatigue are difficult to define and measure; therefore, it is difficult to assess and regulate how to avoid driving while fatigued. As fatigue is difficult to assess through postcrash reconstruction, estimates of the frequency and outcomes of fatigued driving are likely conservative (estimates are 10%–20% of fatigued driving involvement in CMV crashes). Large truck drivers may be hesitant to disclose their level of drowsiness while driving, or the severity of the crash may leave the driver too incapacitated to report this information. Fatigued drivers are more likely to be involved in crashes and are more likely to be involved in higher severity crashes, as their reaction times are often delayed and/or they do not initiate crash avoidance maneuvers (NASEM, 2016). To combat driver fatigue and drowsiness, the FMCSA places limits on drivers' working and driving hours. However, as **Fig. 6** shows, this addresses only one of the factors influencing large truck driver fatigue and drowsiness. Addressing large truck driver drowsiness and fatigue requires a comprehensive approach that includes developing a corporate culture that facilitates reduced driver fatigue; fatigue management education for drivers, drivers' families, dispatchers, carrier executives and managers, and shippers and receivers; screening for and treating sleep disorders; and driver and trip scheduling. The North American Fatigue Management Program addresses all of these topics and can be found at www.nafmp.com.

Impairment From Drugs and Alcohol

Although previous research shows that approximately 30% of all fatal crashes in the United States involved a driver impaired by drugs and/or alcohol, only 3% of these involved CMV drivers. This lower rate may be because FMCSA requires all CMV carriers to have drug and alcohol testing programs. Drug testing through urinalysis is limited to five drugs (marijuana, cocaine, amphetamines, opiates, and phencyclidine). The random testing rates are 50% for controlled substances (drugs) and 10% for alcohol, with about 1% of CMV drivers testing positive for controlled substances and 0.2% for alcohol use. Thus, it appears mandatory drug testing has largely been effective in reducing driving while drugged and/or intoxicated. However, less is known about over-the-counter, prescription, and synthetic drugs (e.g., synthetic marijuana), which may cause CMV driver impairment, but are not part of these testing programs. The Large Truck Crash Causation Study found that 30% and 19% of CMV drivers involved in serious crashes had an associated factor of prescription drug use and over-the-counter drug use, respectively (Federal Motor Carrier Safety Administration, 2006). This may seem like a lot, but to find a causal relationship would require knowing the time the drug was taken in relation to the crash; whether the drug adversely affects performance, attention, and/or decision-making capabilities; and whether the crash was related to the drug's adverse side effects (i.e., not something else, such as speeding). There is no information on the prevalence of synthetic drug use among CMV drivers. Although drug-testing programs are available to identify synthetic marijuana and amphetamines, manufacturers alter the chemical makeup of these drugs at a high rate to evade regulation and detection. Currently, drug tests are conducted through urinalysis. This method can detect drug use in the last 1–3 days. Hair testing, which is permissible for employers to require in addition to urinalysis, can detect drug use in the last few months.

Driver Health and Wellness

Large truck drivers endure a number of physical and psychological stresses inherent to their occupation. The typical lifestyle of a large truck driver may include irregular work and sleep hours, physical inactivity, prolonged occupational sitting, poor eating habits and

nutrition, continuously changing work schedules, and mental and physical stress. These combined factors have major implications for drivers' health, compromising not only their safe roadway performance but also their long-term health. A previous study of 88,246 CMV drivers found that 53.3% of CMV drivers were obese, with 26.6% being morbidly obese, and that 10.2% had diabetes (all outpacing the US prevalence rates (Thiese et al., 2015)). This poor health status of large truck drivers is commonly attributed to lifestyle and occupational factors (e.g., shift work, sedentary work, poor sleep hygiene, improper diet, inadequate exercise, etc.). Unlike passenger car drivers, large truck drivers have more stringent physical qualifications. There are certain physical abilities and medical requirements essential for driving a large truck. These drivers are required to obtain a medical examination card, performed by a certified medical examiner, prior to driving a CMV. The medical examination card can be valid for up to 2 years, though the medical examiner can recommend more frequent medical exams based on a driver's medical history. The FMCSA set the physical qualifications standards for large truck drivers to prevent individuals with certain medical conditions from operating a CMV. There are several disqualifying conditions, including epilepsy, seizure disorders, and vision and hearing impairment. Health and medical conditions, including obesity, cardiovascular disease, diabetes, obstructive sleep apnea, and musculoskeletal injuries, have been demonstrated to increase crash risk. However, treatment of these conditions typically lowers this risk to the level of non-diagnosed drivers. Thus, large truck carriers should focus on prevention and treatment of these medical conditions to increase the health of the large truck driver population (as well as reduce crash risk).

Speeding

Compared to light vehicle drivers, large truck drivers are more likely to follow posted speed limits. However, when these drivers do travel above the posted speed limit, or when they travel too fast for conditions, they are more likely to be involved in a crash. In fact, traveling too fast for conditions is the second most common contributing factor in large truck–light vehicle crashes. Furthermore, when a speed-related crash occurs between a large truck and a light vehicle, the collision will be more severe than a lower speed crash. As large trucks in the United States can weigh up to 36.28 metric tons (80,000 lb), the damage resulting from a crash increases exponentially the faster the large truck is traveling.

In an effort to address the deadly consequences of speed-related crashes involving large trucks, these trucks are typically equipped with speed limiters. Speed limiters (also known as speed governors) work to limit the speed of the large truck to a predetermined maximum speed. Although there are no current federal regulations mandating the use of speed limiters or dictating the speed to which they are set, many fleets have policies regarding their use. In a previous study, researchers evaluated the efficacy of large truck speed limiters in preventing crashes (Hanowski et al., 2012). This study analyzed data from over 150,000 large trucks and 28,000 crashes. Large trucks governed by a speed limiter had a speed-related crash rate of 1.6 crashes per 100 trucks/year, and trucks that were not governed by a speed limiter had a speed-related crash rate of 2.9 crashes per 100 trucks/year. This represented statistically significant differences where trucks governed by a speed limiter were involved in fewer speed-related crashes compared to trucks not governed by a speed limiter. Other research has also shown that telematics-based devices, when paired with driver feedback and management follow-up, can significantly reduce speeding.

Advanced Driver Assistance Systems

ADASs, sometimes referred to as adaptive driver assistance systems, are electronic systems that provide safety-related support to a driver. Though several types of ADAS technologies exist, the overall purpose of an ADAS is to promote safety. Most new vehicles manufactured today include the option to use some type of ADAS technology, typically as part of a safety or electronics package. Adaptive cruise control, forward collision warning, lane departure warning, adaptive headlights, blind spot detection, and automatic emergency braking are just a few of the ADAS options that are available. Though research is ongoing with respect to the measured safety benefits for these ADAS options, research to date has been positive (Fig. 7).

Basic ADASs provide timely information to support the driver in making safe, informed decisions. Embedded sensors focus on a specific application to support driver decision-making. For example, blind spot detection systems monitor traffic in the lateral spaces adjacent to the vehicle and provide an indicator, usually on the side mirror, informing the driver if there are vehicles in the blind

Figure 7 Blind spot detection.

spot. This information lets drivers know that it would be unsafe to change lanes at that moment (when the side-mirror indicator is “on”). More updated ADASs provide interventions (beyond information only). Automatic emergency braking systems, for example, monitor traffic in front of the vehicle, calculating time-to-collision. If the calculated time-to-collision falls beneath a predetermined threshold, which would indicate a potential forward crash scenario, a warning indicating the need for the driver to press the brakes is followed by automatic braking by the vehicle if the driver fails to respond. These more updated ADASs will, regardless of the driver’s actions, intervene if an imminent collision is detected.

Automated Driving Systems

A key aspect of these technologies is that individual ADASs provide the building blocks to make autonomous driving possible. That is, individual ADASs that are “layered” together, along with additional sensors, maps, and software, work collectively to support automated driving systems (ADSs).

Consider again the situation with automatic emergency braking: if the driver fails to recognize a forward crash imminent situation, the vehicle will brake *for* the driver. In this scenario, the driver is not in the response loop and is not needed for the brakes to be depressed. ADSs, then, represent a broad array of such technologies that provide control input to safely operate the vehicle.

SAE International has outlined various levels of automation (and control); Fig. 8 describes the six automation levels that range from “no automation” to “full automation.” This spectrum of automation levels highlights the involvement of the human driver. In all but the most advanced levels (4 and 5), the driver remains “in the loop” and, thus, has ultimate control of the vehicle’s operation.

Though many examples of lower levels of automation exist, most industry experts agree that full automation is likely many years from realization. Furthermore, beyond the technological hurdles that must be overcome, implementation of ADS in large truck fleets has many other issues that can only be resolved with the development of a concept of operations. Fig. 9 highlights some of the key contextual aspects that need to be in place before ADS can be implemented on a meaningful scale in the United States.

Figure 8 SAE levels of automation.

Figure 9 ADS concept of operations.

Inspection Level	Description
I	Includes a review of carrier and driver credentials, logbook or electronic logging device, an inspection of the vehicle's condition, and an inspection of all hazardous materials or dangerous goods.
II	Includes a review of driver credentials, a walk-around vehicle inspection to check components that do not require getting under the truck.
III	Includes only an inspection of driver credentials.
IV	A special inspection of a particular item and is usually conducted as part of research or to investigate a suspected trend.
V	Includes only an inspection of the vehicle that can be conducted without the driver present at any location.
VI	Includes an inspection of transuranic waste and route-controlled quantities of radioactive material.
VII	An inspection jurisdictionally mandated.
VIII	An inspection conducted electronically while the vehicle is in motion, without direct interaction.

Figure 10 CVSA commercial motor vehicle inspections.

Large Truck Roadside Inspections

In the United States, the FMCSA is the federal agency charged with reducing crashes involving large trucks and resulting injuries and fatalities. To do this, FMCSA maintains and enforces the Federal Motor Carrier Safety Regulations. FMCSA has established several tools to support its enforcement efforts, including the compliance, safety, accountability program, and the safety measurement system. The safety measurement system ranks motor carriers based on their safety performance, which is determined using data collected during roadside inspections (e.g., the frequency of different types of violations and the frequency of crashes involving the carrier). This system was developed to prioritize unsafe, high-risk motor carriers for targeted interventions.

Currently, in the United States, approximately 3.5 million inspections are conducted annually to ensure the safety of large trucks and buses operating on our roadways. Highly trained inspectors in each state inspect CMVs using inspection procedures developed by the CVSA. These procedures and criteria are part of the North American Standard Inspection Program and currently include eight levels of inspection. Level I, which is the most common, involves the examination of the driver's credentials and record of duty status along with a detailed inspection of the vehicle's mechanical condition. **Fig. 10** provides the CVSA levels of inspection and associated procedures.

Violations arising from these inspections are recorded in the Motor Carrier Management Information System. FMCSA uses this system's data to identify carriers that are out of compliance with federal regulations and good candidates for targeted safety interventions. The Motor Carrier Management Information System contains carrier registration details, information from inspections and interventions, and violation and crash data. Research on the effects of roadside inspections has shown a strong relationship between quality maintenance and inspection procedures and a decline in crashes related to vehicle defects. Research found that the defects most likely to cause crashes were those associated with brakes, tires/wheels, and lights. Additionally, vehicle inspections and application of the out-of-service criteria through the roadside inspection program have significantly decreased the rate of truck crashes in which mechanical or safety defects were cited as a primary contributing factor ([Lantz, 1993](#)).

Conclusion

There is a growing body of evidence that the safety countermeasures described earlier prevent large truck crashes and their associated injuries and fatalities. These countermeasures include management practices to improve fleet safety culture, education and training programs targeting driver health and wellness, safety-related devices to reduce large truck speeding, ADAS to assist drivers and control the vehicle, and enforcement activities to improve vehicle maintenance. Although research showed these countermeasures to be effective in preventing crashes, fleets should focus on a comprehensive mix of countermeasures rather than viewing any single countermeasure as a "quick fix."

Demerit Point Systems and Their Variations

A demerit point system (DPS) is a traffic law enforcement practice aimed at increasing road safety by preventing and correcting dangerous behavior in traffic. The point systems implemented in many countries around the globe take different forms in each of them. Locally, a DPS can also be referred to as a point system or penalty point system. Penalty points usually accompany other types of sanctions, such as fines or the possibility of imprisonment. Every traffic law offence included in the point system is recorded within the system for each driver. Misconduct on the part of a driver leads to them receiving or losing a certain number of points for their transgression and, after the driver reaches a critical number of penalty points, penalization follows, which can ultimately lead to the suspension of a driver's license. The license can be returned after a certain period of time has passed and sometimes only after the driver meets necessary requirements, such as reeducation, assessments, or tests. The advantage of the system lies in its fairness for drivers, who are granted equal treatment, while also allowing specific high-risk groups to be focused on, so that, for example, habitual offenders can be penalized more harshly for incessant repeated offences, which can result in lower tolerance within the system (gaining more points per offence or the suspension of the license being of a longer duration each time). It must be noted that this fairness has its limitations as a result of the following facts. There might be a bias on the part of police officers toward certain drivers when charging them; for example, a police officer may be more likely to charge young drivers with speeding than older ones or decide to give oral warnings in some cases and tickets leading to demerit points in others. Additionally, the randomness of Poisson distribution has to be taken into account. This means that in reality some drivers get more or fewer fines (and points) even though they commit the same number of violations as an "average" driver (Evans, 2004). The equality of treatment has justified exceptions regarding certain groups, such as novice or professional drivers. DPSs are especially widespread in Euro-Atlantic countries, but are becoming popular worldwide. To date, such systems have been implemented in the vast majority of European Union member states, in Australia, Canada, New Zealand, and the United States of America, but also on other continents, in countries such as Brazil, South Korea, Malaysia, Singapore, Morocco, the United Arab Emirates, and South Africa. When it comes to DPSs, no two countries are alike. In some countries, drivers start with zero points and accumulate penalty points for each offence, while in other countries they are given a fixed number of points at the beginning and demerit points are then subtracted for each traffic law violation. Countries and states using DPS have lists of offences that are penalized by a given number of penalty points being assigned. In some countries, each offence has the same weight and the driver receives one point per offence, while in other countries different transgressions are penalized by different numbers of points being assigned; typically, the more dangerous the behavior (such as speeding), the more severe the punishment. In the case of speeding, in some countries, the law takes account of the speed in excess of the legal limit. Typically, the number of points given for a specific offence is set by the law, but in some countries, the number of points assigned can be flexible and might also depend on a court decision. Countries also differ in the number of demerit points resulting in drivers having their license suspended, in the types of offences subject to penalty points, in the types of rehabilitation programs that make it possible to erase or acquire points, as applicable, and in the process leading to the restoration of the driving license. Certain countries distinguish between various driver groups, such as professional and novice drivers, who come under special terms and conditions, and some even use DPS only for novice drivers (e.g., the Netherlands). In addition to the earlier criteria, countries also differ in terms of the complexity of the system, the authorities involved in the process, the transparency of the system, drivers' access to information about their current point status, and the inclusion, or exclusion, of foreigners in the DPS, as well as in whether nondrivers are included in the system.

Demerit Point Systems as a Preventive, Selective, and Corrective Measure

Road risks stem from human error rather than from the imperfection of the system, as the human factor is involved in 90%–95% of road accidents. Nevertheless, the nature of the human factor is too complex to make it possible to formulate simple conclusions and recommendations. Driving is such a complex and diverse activity that it is impossible to identify several individual qualities that

could help us distinguish safe and responsible drivers from dangerous and irresponsible ones. In addition, drivers are in no way a homogeneous group, which prevents the generalization and interpretation of available evidence. On the contrary, the number of traffic law violations is one of the best single predictors of future involvement in accidents (Elvik et al., 2009). Previous accident involvement is an even better predictor. The DPS works on the principle of improving road safety by deterring road users through the threat of punishment (on a general level) and through sanctions for those who are caught and convicted (on a specific level) (Sagberg and Sundfør, 2019). The specific deterrent effects can be evaluated by the monitoring of the reoffending rate, the general effects by the prevalence of negative phenomena among the driving community (e.g., lower rates of speeding or crashes) (Sagberg and Ingebrigtsen, 2018).

A DPS may affect violations and accidents through three mechanisms: prevention, selection, and correction. The *preventive* effect of a DPS lies in the risk of losing one's driving license if caught offending repeatedly. The general preventive effect should be found in a decrease in the number of offences for all drivers: they drive more carefully in order to avoid getting a demerit point (Sagberg and Sundfør, 2019). The other preventive effect is providing drivers with negative feedback on their risky driving (Sagberg and Sundfør, 2019). The absence of negative feedback leads to drivers having a false belief in the low probability of accidents and in their perception that they have a higher chance of avoiding a road accident in comparison to others. The absence of social negative feedback is addressed by the DPSs.

As for *selection*, if a DPS can exclude road users who often engage in dangerous behavior from participation in traffic before they could actually cause a crash, it can improve road safety (Klipp et al., 2011). But a DPS can only be an effective means of selection if demerit points or offences are indeed a good predictor of future crashes and if repeat offenders are tracked down in time. Particularly serious offences (involving many demerit points) are good predictors of future crashes. This relationship is at its strongest among young novice drivers. Systems in which drivers can have the number of their points reduced by following a driver improvement measure have an educational element that is intertwined with the preventive effect (*correction*) (Klipp et al., 2011). DPSs with educational elements can only work if it is proved that a course is effective and results in a change of behavior in a desired direction.

An added benefit of a DPS is that it takes recidivism into account: repeat violators of the rules are punished more severely.

Underlining Theories

In terms of its theoretical framework, a DPS can be designed and implemented effectively on the basis of what is referred to as the *3E* model (including its extended versions), which proposes approaching road users from three different perspectives: *Education and Training*, *Engineering*, and *Enforcement*. If we want to achieve a real change in road users' behavior (as regards better safety, or the elimination of risky behavior), we need to exert an influence on road users on all three of these levels. In terms of DPSs, the key areas are Education and Training and Enforcement.

Empirical evidence shows that effective and just enforcement has an impact on road users' behavior with regard to the reduction of risky behavior. The following conditions must be met for enforcement to be effective:

- People must know the rules (i.e., they need to know which behavior is correct and expected).
- They must be able to apply such knowledge (i.e., they need to possess relevant skills and be able to behave according to their knowledge).
- The benefits of breaking the rules must be smaller than the loss ensuing from the imminent sanction (i.e., they need to be motivated).

The positive effect of enforcement on road safety is an increasing function of certainty (that one will eventually be caught), strictness (the sanction being significant enough for the violator), and the imminent threat of being sanctioned (a person cannot avoid punishment).

The concept of deterrence is based on the principle that "prevention is better than punishment." However, deterrence is never the only and primary aim of legislation (the legal system). The substance of deterrence is the threat of punishment taking the form of a certain sanction. Deterrence is a way of gaining control on the basis of fear. If drivers commit violations without being concerned about the consequences, then deterrence is ineffective by definition. In general, deterrence involves behavior control, which occurs in a situation where a potential perpetrator is not willing to take the risk of certain behavior out of fear of its consequences. Deterrence is thus one of the mechanisms for achieving compliance.

Punishment deters the potential perpetrator from illegal behavior (a process which may be referred to as *individual prevention*) while also deterring other individuals from potential offending (*general prevention*). It can be assumed that every person knows what is permitted and what is not and is also aware of the consequences of illegal behavior. People's experience of punishment, both indirect (e.g., experienced by a friend) and direct, reduces their inclination to offend, as it enhances their perception of the risk of being sanctioned (Sagberg and Ingebrigtsen, 2018). According to the deterrence theory, punishment is regarded as a means of discouraging people from committing both administrative and criminal offences. The effects of punishment can be divided into several groups.

- The first encompasses the aforementioned theory of general prevention, which further breaks down into negative and positive categories: the negative theory of general prevention proposes that the threat of punishment would discourage the perpetrator from committing an offence (Sagberg and Sundfør, 2019). The positive theory of general prevention proposes that the inevitable

strict punishment imposed within a short time after the offence being committed will strengthen people's trust in the judicial system.

- The second group is represented by the theory of special prevention: it is assumed that strict punishment imposed on the offender according to the law would also be a sufficient deterrent for others.
- The third type is the theory of individual prevention. It is based on the notion that the harm suffered by the perpetrator as a result of the punishment they received would dissuade them from continuing to engage in illegal activities without any additional educational measures being used (Lee et al., 2018).
- The fourth is the rehabilitation theory, which proposes that a violator's illegal acts are due to various factors (including family, upbringing, social circumstances, and psychological traits), which influence their behavior and development. Here, the purpose of the punishment is to provide professional help, which will make it possible for the perpetrator to gain an insight into their characteristics, and behavior and the social influences, which resulted in their offending. The rehabilitation theory involves efforts to reintegrate the perpetrator into society on the basis of a change in their behavior occurring as a result of their understanding that such behavior is socially problematic.
- Finally, there is the restitution theory, which underlines the need to compensate for damage and harm caused by illegal conduct. In this respect, crime is perceived as a threat to society, and harm caused to the victim must be redressed.

In practice, these theories are interlinked in such a way as to ensure that traffic-related sanctions fulfill the purpose of the punitive policy of the state as regards public safety, resocialization of offenders, and compensation for damage done, as well as the deterrence of potential perpetrators.

The basic 3E model can be extended to include other "Es" with relevance to the implementation of the DPS:

Education and Encouragement—that is, raising public awareness about the purpose and implementation of the DPS and seeking to win over the public and build its commitment and engagement.

In addition, *Evaluation* is there to test whether the strategies used are working, particularly in terms of the number of traffic violations and accidents and their levels of severity.

Driver Improvement Measures and Intermediate Measures Within Demerit Point Systems

Both research and empirical studies seem consistent in their conclusions about the compatibility and synergy of DPSs and driver improvement measures. For example, the recommendations issued as part of Bestpoint, the largest European project of its kind, are clear in this respect. A DPS is effective if it incorporates a focus on specific groups, such as repeat offenders and professional drivers, by promoting driver improvement courses for perpetrators of serious violations and for those who use up all their penalty points. In addition, Bestpoint recommends driver improvement measures aimed at attitudes and behavior change rather than knowledge and skills. The key question regarding driver rehabilitation measures and DPSs is whether and why training in dealing with critical situations is a wrong path to take. While driver rehabilitation programs are intended to improve drivers' attitudes and enhance their will to abide by the rules, the basis of safe driving courses is to develop drivers' skills. These measures thus lie at opposite ends of the spectrum of measures aimed at enhancing road traffic safety. No matter how sensible it may sound that teaching people emergency braking or skid control helps in reducing the impact of hazardous situations, long-term experience from other countries indicates the opposite effect. The beginning of the criticism of this type of training dates back to the 1980s. There is a strong empirical evidence showing an increase in the number of skidding-related accidents after this type of training was made a mandatory part of the driving schools' curriculum. Following the introduction of safe driving courses, a great proportion of novice drivers' accidents occurred on slippery roads. The explanation might be that safe driving courses involved training in skills to control the car that resulted in an unreasonable increase in drivers' confidence in their own capabilities. Instead of using these capabilities in emergency situations, individuals who had completed these courses used them under regular circumstances, which led, for example, to their driving at higher speeds. Moreover, graduates of these courses overestimated their abilities; their actual skid control abilities did not differ from those possessed by drivers who had not been on the course. Evidence shows that: (1) drivers, and often also instructors, failed to understand the main point of the course, which is that safe driving under slippery conditions is about avoiding an emergency situation rather than dealing with one; (2) skills learnt in this way do not last for long; (3) the most skilled drivers show much higher accident rates, and, most importantly, (4) effective driving courses feature work with attitudes, risk perception, experience, and knowledge rather than training in skills. Generally, it can be stated that any courses based on training in skills to cope with emergency situations will eventually result in greater accident rates and worse road safety and thus they should not constitute a part of the DPS. Therefore, the European Conference of Ministers of Transport identified these courses as inappropriate for young drivers and, subsequently, the European Road Federation, drawing on long-term evaluations, issued recommendations for the European Commission that these courses should be eliminated from the driver education and training system.

The Effects of Demerit Point Systems in Terms of Lower Rates of Accidents and Fatalities

Experience clearly shows that the introduction of DPSs leads to reduced rates of traffic accidents and road fatalities (Klipp et al., 2011). This effect is particularly visible in the first years following the establishment of the measure but tends to diminish over

time. It was found that DPSs were effective in reducing the rate of road injuries and fatalities by up to 20%. Studies suggest that DPSs result in a reduction in the number of accidents and casualties. Alternatively, the effectiveness of DPSs is indicated by analyses of medical records of road accidents, which also show significant reductions following the introduction of these systems, for example, a reduction in the rate of spinal injuries suffered in road crashes. Overall, meta-analyses and reviews demonstrate positive outcomes of demerit points, especially when they are accompanied by additional measures and public campaigns. However, this effect was found to decline dramatically 18 months after the introduction of these systems. One reason for this may be the reduced effort on the part of governments to support the DPSs with accompanying measures. Without additional supporting measures, people's initial fear of losing their driver's license tends to fade quickly, as the perceived risk of being caught diminishes over time.

The effect of the DPS on preventing recidivism depends on the perception of sanctions by drivers. The most important aspect appears to be the certainty of punishment, while, regarding the general level of deterrence, an increase in the severity of the punishment has only a minor effect on people's repeated engagement in risky behavior and a change in their behavior. The severity of sanctions is an effective factor in the event that the probability of being caught and punished is very high. However, this is particularly difficult with hard-core recidivists, as these display several differences in comparison with other drivers. They consider the risk of being caught as lower, the benefits from committing traffic offences higher, and the losses related to offences lower. Consequently, a large number of drivers with custodial sentences return to prison within 3 years. Regarding drinking and driving, we can see the effect of a lifestyle associated with addictive behavior. Those who drink more also engage in drink driving more frequently, while those with low or medium alcohol consumption are better at refraining from impaired driving.

It must be noted that it is quite complex to determine the effect of a DPS. In addition to the point system, multiple other factors are often involved and these factors change over time and influence the number of crashes. Furthermore, the introduction of a DPS nearly always coincides with an (unfortunately only temporary) increase in enforcement and with public campaigns. It is therefore impossible to establish the extent to which the effects can be attributed to each factor. Accordingly, it is very difficult, in practice probably impossible, to evaluate the effects of a DPS in a way that could be regarded as scientifically rigorous. First, the introduction of a DPS is generally accompanied by significant media coverage and an increase, or proclaimed increase, in enforcement. Sometimes, it also goes together with new rules and regulations. In addition, since a DPS is always introduced on a nationwide scale, it is impossible to include a good reference group. Consequently, it will remain largely unknown whether observed changes in behavior or in the number of casualties are the result of the DPS or whether some or all of such changes should be attributed to the enforcement, publicity, or other unknown factors.

DPSs may also have some undesirable side effects that should be taken into account. The first one is driving without a driving license. If a penalty hits a motorist hard, but the enforcement of the penalty is weak, the driver will soon be inclined to ignore the penalty. In some countries, up to 40% of the drivers whose driving licenses had been suspended because of the DPS admitted in a survey to continuing to drive. The second one is hit-and-run incidents. The inclination to drive on after causing such an incident will increase out of fear of receiving additional points. No objective figures about the size of these undesirable side effects are available. Finally, there is the buying and selling of points (also referred to as "points trafficking"). If a DPS takes account of automatically detected offences as well, and the driver cannot be identified, it must be found out from the registered license holder who the driver was. This may lead to paying others with no or few points or nonactive drivers who are willing to take the blame for the offence. Objective figures about the size of this problem are lacking.

Recommendations for the Implementation of a Demerit Point System

It is important to have public support for a DPS to ensure its proper functioning. When people understand the principles and agree with them, they are more likely to be compliant with the rules as proposed. If it is otherwise, they might be repulsed by the unwanted. This can be explained by the concept of resistance, when imposed rules boost disobedience merely through one's feeling that one's freedom is being restricted. Typically, the public favors penalty systems, but, to keep the system popular, we should strive to create and keep equal and transparent conditions for all drivers. It is also essential to communicate the beneficial aspects of such systems, as this can help in sustaining their effectiveness. The system should not be too complex—all drivers should be able to understand it (it should be noted that many different people become drivers). In this way, better compliance can also be achieved when the system is viewed as fair.

Although everybody should perceive the system as fair, it is necessary to focus on those who pose the greatest threat to road safety, the minority of drivers who are more likely to take risks and violate the rules, specifically novice young drivers, habitual offenders, and those who drive under the influence of alcohol and drugs. Being responsible for a great proportion of traffic incidents, young drivers represent a high-risk group of drivers. Some countries use DPS for novice drivers only for a certain number of years after they obtain their license, while others have special, stricter conditions for this group, including a smaller number of points before a license is suspended. This measure has an important educational aspect: having to deal with stricter rules from the beginning of their driving careers, they have a better chance of developing good driving habits. Carefulness in driving aimed at not losing points can make them less likely to engage in dangerous driving. Their careful driving attitude can then serve as a good foundation that is more effective than initial leniency followed by later efforts to teach the right behavior when driving habits have already become established. Regarding professional drivers, it is recommended that offences peculiar to this group of drivers, such as compliance with rest times and good technical condition of the vehicle, are included. In addition to

novice drivers, drug and alcohol users represent another high-risk group. These should be tested for substance use and have their licenses suspended in the event that such tests show positive results. While in recovery, these drivers should only be allowed to drive cars equipped with an alcohol interlock device. It is necessary to ensure that they get specialized long-term medical and psychological treatment, as one-off interventions do not suffice. The group of habitual offenders must be dealt with similarly: they need to undergo thorough rehabilitation leading to a behavior change.

Usually, the points are awarded to car drivers or drivers of all motorized vehicles. There is nevertheless discussion among experts as to whether offences committed by other road users should also be registered by the system. Although it would make the system more complicated, the fact remains that all parties, including cyclists, motorcyclists, and pedestrians, must participate in creating a safe traffic environment and each of them should anticipate errors on the part of other road users. Shared responsibility could encourage more consideration and carefulness from drivers, cyclists, and pedestrians and might improve overall road safety. A record in the system of nondrivers having committed a serious traffic offence could be considered in the future when they apply for a driving license; their previous misconduct could even prevent them from obtaining a license.

Given that foreign drivers usually have to pay only fines for traffic offences committed abroad, they are not motivated to exercise greater caution while driving. Having an international register of the points collected by each driver could encourage drivers to become more compliant no matter where they are. The penalty points given in a certain country could be converted to the equivalent number of points which are assigned for specific offences in the driver's home country. In this way, the offence would be transferred into the driver's country of residence, with any implications this may entail.

Demerit points can be assigned for a number of violations. The Bestpoint project suggests penalizing at least those offences directly connected to safety, namely, speeding, driving under the influence of drugs and alcohol, running red lights, overtaking, crossing priority rules, not keeping the minimum distance, the use of mobile phones, dangerous behavior at pedestrian and railway crossings, driving in forbidden lanes or in the opposite direction, involvement in hit-and-run incidents, and not using seat belts, helmets, and appropriate child restraints. The number of penalty points assigned usually reflects the severity of offences, although some countries register one point for every offence. It is recommended to relate the number of points to the degree of the impact they can have on road safety, especially on crashes and the severity of their consequences. This practice would allow the predictive power of the previous violations of the rules to be used and prevent the most dangerous drivers from road use before they can cause harm while also communicating to drivers what the most dangerous behaviors are (Martensen et al., 2018).

Typically, after a certain period of time has passed, a certain number of points are erased. The lifetime of a point should correspond to the severity of an offence and the points should be erased on condition that within a given time period no new penalty point is recorded. The reward in the form of the points being deleted could motivate drivers to become more careful. Moreover, according to the self-perception theory, when drivers are freshly motivated to obey the rules, they begin to view themselves as good drivers, which strengthens their newly emerged good behavior.

When drivers accumulate a certain number of points, it is recommended to take a three-step approach to applying driver improvement and intermediate measures: send out information and warning letters, have their license temporarily withdrawn, and require them to participate in a driver improvement course aimed at bringing about a change in their attitudes and behavior before their license is renewed (Elvik et al., 2009). Sending a warning letter after a certain amount of points has been reached reduces the risk of a crash (Elvik et al., 2009). The drivers are made aware that the withdrawal of their license is a real threat, and some drivers may not even be aware of the fact that they have been given penalty points (Sagberg and Ingebrigtsen, 2018). A similar effect can be achieved by ordering drivers who have reached a certain point threshold to attend obligatory interviews where they have to present arguments explaining why their license should not be suspended. When the point threshold is reached, offenders have their driving license suspended. The suspension period should be neither too short, as it would not have the intended deterrent effect, nor too long, as it could encourage drivers to drive without a driving license. The ideal time is at least 3 months and no more than 1 year. Repeat offenders should have a longer disqualification period every time their license is suspended. License restoration should be tailored depending on the offence, especially with regard to habitual offenders, aggressive drivers, and those who drive under the influence of drugs and alcohol. The reeducation should be proved to be effective, as often it does not bring about the intended change, and the rehabilitation should aim at behavior change, which can be achieved through traffic-specific psychological counseling.

Both communication and enforcement are indispensable for a DPS to be successful and have a positive effect. It will hardly be possible to maintain the positive effects of the system without a sufficient level of enforcement and the driver's experience that the detection of offences is a real threat. The latter can be achieved by the automated detection of certain offences and increased police involvement in surveillance and testing. People should be aware that it is highly probable that their traffic violations will be detected by the police. An essential element of effective enforcement is the perceived risk of being caught when committing an offence. Obviously, the subjective chance is largely determined by an objective, real chance of being caught. In this respect, the major role played by communication campaigns and media coverage of enforcement operations and their aims and results should be noted. Enforcement should be unpredictable, so that drivers do not have the opportunity to adapt quickly to expected checks and return to their old ways in a short time. Communication means that people must be aware that there is a DPS in place and understand how it works. The campaigns should aim at setting positive social norms, as well as making it clear that offenders will be punished.

To ensure its proper functioning, each DPS must be evaluated for effectiveness. Without it, such a system might turn into a costly measure that falls short of the expected results (Martensen et al., 2018). Countries that are considering implementing a penalty point system should assess whether they are prepared for it in terms of the level of enforcement and campaigns to ensure that drivers will take the system seriously and adjust their behavior accordingly.

Mental Workload

Mental workload is a concept that people can relate to; at the same time, it is not clear whether all have the same concept in mind. For many people the difficulty of a task equals mental workload. In many ways that is not such a bad representation, as difficulty is very subjective. In fact, one of our main points is that; as with physical workload, mental workload depends not only on the task that one has to perform, but also on the person concerned. Therefore the level of mental workload is not constant between or within individuals.

The idea that mental workload can be quantified probably originates from its comparison with physical workload. For physical work, the force required to move an object can be defined in Newton, representing what is required to perform a task. However, it is more difficult to define mental workload. One could try to quantify the information-processing demands (for example, the number of calculations that are required to solve a problem). Crucial, however, is the individual capacity to perform these operations— for physical workload as well; moving 60 kg is easier for a physically fit person than for a fragile child. For physical workload, however, we tend to focus on task demands, while for mental workload we take the capacity to perform a task into account. In other words, with mental workload we must also consider the interaction between task demands (the task to perform) and the capacity to perform the task. The latter, also referred to as mental resources, provides a link to operator state, the background state of an individual. State differs not only between but also within individuals. The same task may require different mental resources for a novice and an experienced person—difficult for the first, easy for the second. Additionally, the capacity to perform a task differs within an individual; for example, after a bad night's sleep the task normally considered routine will be experienced as far more difficult to complete.

This brings us to another important concept in mental workload: effort. Effort is a voluntary process, which can best be described as trying hard. The result of effort can be that the performance is maintained at an acceptable level, that is performance is protected, but internally there are (energy) costs. There are two types of effort: *computational effort*, task-related effort (to deal with the increased demands of a task), and *compensatory effort*, state-related effort (to counteract a deteriorated state). In Fig 1 this is graphically illustrated: it shows the relation between task demands (x -axis) and the level of performance and mental workload (y -axis) (De Waard, 1996).

Above all these considerations is self-regulation: deciding how the different task demands are managed. This can mean accepting a lower level of performance or changing to a more efficient strategy to accomplish the goal.

In sum, task demand is a property of the task to be performed. Mental resources are the capacity to perform a task, and they depend on short- and long-term factors such as experience and operator state. With the investment of mental effort, performance can often be kept at an acceptable level. Investment of effort is an effective mechanism, but it incurs costs so it cannot be continued over long periods of time.

The next section focuses on car driving.

Mental Workload During Driving and Driver State

During a drive, a driver's task demand can vary substantially, for example, the drive can start in a busy city but then continue on a quiet highway. In addition, each individual driver has certain characteristics, some may be novice, some professional, or, the most

likely, somewhere in between. For a novice, protecting performance (driving safely without getting into a collision) can require continuous effort investment taking up most of their mental capacity, while for the professional enough mental capacity is left over to do other things, such as operating the radio. During a journey, driver state is also likely to change. Driver state is the driver's mental and physical condition, often reflected in physiological parameters such as an electroencephalogram (EEG). The environment plays an important role here. While monotonous, quiet highways at night are ideal circumstances for driver state to deteriorate, the opposite—when roads are extremely busy—could overload drivers. Imagine being overloaded by information in an unfamiliar city and trying to find your way with an uncooperative navigation device that continues to ignore the roadwork and keeps on nagging that you should turn left when turning left is not possible. On the other hand, low task demands could stimulate drivers to do things other than driving, such as using their mobile phone. The question is: how can we ensure optimal driving performance under these very different circumstances in order to secure safety and comfort? The driver who can regulate task demands also plays a role. For example, many older drivers seek to keep task demands low by avoiding complex traffic situations, such as driving at night, or adverse weather. However, if the weather suddenly changes or the preferred familiar road is closed, task demands may become very high for them, and bring them in an uncomfortable situation. The main message, however, is that people adapt to the tasks they perform in a way that in their perception is comfortable and not stressful.

Mental Workload and Driver State in Partly Self-Driving Vehicles

We are currently transitioning towards fully automated driving (Van Nes and Duivenvoorden, 2017). In the meantime, the use of driver support systems has increased, and an increasing number of vehicles are partly self-driving (also referred to as semi-automated), meaning the automation can take over part of the driving task or even that the car can drive by itself in certain conditions (the autopilot function for the highway). New systems are constantly being introduced to support the driver in the driving task. Systems such as Advanced Cruise Control (ACC) and Lane Keeping Systems (LKS) take over parts of the driving task; the ACC removes the mental load of maintaining a certain speed and keeps a safe distance from a lead vehicle, while the LKS takes care of lateral positioning. As more systems are introduced, more tasks are being taken over by automation. The role of the driver is slowly shifting from operator of the vehicle to a supervisory role, which is extremely monotonous. As a result, even though the task demands and mental workload are reduced, supervising a (partly) automated vehicle without an active role has a negative effect on driver state. From a safety perspective, the priority is to keep driver workload in the “optimal performance” window (central area in Fig. 1). State-related efforts to maintain the performance for longer periods of time should be avoided, but drops in performance (right hand side of the graph) are even worse.

Another potential risk is introduced by the temporary increase in task demand created by these systems themselves. Each system communicates to the driver in some way, giving warnings (blind spot warning, forward distance warning, etc.) and/or indicating the status of the system (on, off, or changing). With an increased number of systems, communication demands also increase. Different signals can be confusing or contradictory, leading to increased mental workload. Another increase in workload is caused by the fact that the driver has to be continuously aware whether systems are on or off and understand the systems' limitations—and check whether these may apply. It is therefore just as important to avoid too much increase in mental workload due to task-related effort requirements (Fig. 1).

Clearly, the use of driver support systems and partly self-driving vehicles impact task demand, leading to possible overload or underload, two situations that impact driver state and task demands. Thus there is the risk of leaving the optimal performance window, resulting in degraded driving performance. In the transition towards higher levels of vehicle automation, it is crucial to mitigate this risk and ensure drivers stay within the optimal performance window. Every level of automation should be designed in such a way that the optimal performance window is respected, which would require settings that can be changed.

Figure 1 Increasing task demands (x-axis); task performance, and mental workload (y-axis). Source: From De Waard (1996).

Clearly, higher levels of automation offer the opportunity to mitigate driver workload. An interesting way to manage this effect would be to continuously monitor driver state during a trip to determine if it stays within the optimal performance window, and take measures if needed.

Assessment of Mental Workload and Driver State

Given the potential negative effects of mental underload/overload on driving behavior and safety, correct assessment of the driver's mental workload and state are crucial. There are three types of measures that can provide an indication of mental workload and driver state: performance, self-reporting, and psychophysiology (Paxion et al., 2014).

Performance

An assessment of mental workload and driver state should start with driving performance. In driving, primary task performance is reflected in lateral and longitudinal control. Both lateral control, that is the lateral lane position, and its variability (standard deviation of the lateral position: SDLP) have been used for a long time to reflect driver state. SDLP is sensitive to many factors, including the use of sedative drugs such as alcohol, distraction, and fatigue. Mean lateral position can reflect strategic choices: it has been shown that drivers who noticed the sedative effects of medicinal drugs drove closer to the emergency lane, where more space is available. Longitudinal control is reflected in the vehicle's speed and speed variability and distance to other vehicles (time headway). The latter measure is always in interaction with other vehicles and frequently a car following test is used where a lead car changes speed and needs to be followed at a close but safe distance. In this test, driver response time (delay in sensitivity to speed changes) can be calculated (Brookhuis et al., 1994).

In addition to primary task performance, which reflects the behavior to control the vehicle safely, there is secondary task performance. Secondary tasks are frequently used by researchers "to fill up the capacity of the driver." The idea is that with an extra task that is demanding, the driver will no longer have the spare capacity that is usually not required for normal driving. Instead, the secondary task will require this spare capacity, causing performance on either the primary driving task or the secondary task to deteriorate. In this way we are able to see, for example, which parts of a route are more demanding and resulted in higher workload. For the secondary task an artificial task is very often used. One such example is the N-back task: the driver has to remember a stimulus (a letter or a figure, the target) that was presented N stimuli back, and indicate whether it is presented again. The target has to be updated continuously. As N increases, the task can become very demanding. Another example is the peripheral detection task: drivers have to respond to a light that is presented in their peripheral vision. Both techniques are popular, but they also have major drawbacks. To start with, they are artificial. During normal driving you do not have to keep a memory set in mind and respond to it. Even though the peripheral detection task has some ecological relevance in the sense that a driver may have to respond to stimuli in the periphery, the task is still artificial because in normal traffic this need is seldom a continuous task (and the stimuli are, for example, pedestrians or other cars, not a red light). In other words, normal driving may be distorted. Moreover, we do not know which task the driver prioritizes, the secondary task or the primary task. However, there are embedded secondary tasks (that are part of normal driving): an example is mirror checking. Glancing in the rear-view mirror is a part of safe driving, but it is not a crucial task if one is not changing lanes. It has been shown in on-road experiments that the frequency and duration of mirror checks can change. For example, the frequency drops if the driver is operating a telephone or driving in a busy environment.

Thus, primary task performance (vehicle control) must be assessed when evaluating mental workload. If a secondary task is used, it should be clear that it does not affect normal driving, which in practice is difficult. An embedded secondary task is preferred.

Self-Reports, Subjective Measures

Asking how demanding a situation was for a driver has always been a popular technique to assess workload. It definitely makes sense to ask people how they experienced a situation, as this gives information that cannot be assessed in any other way. Simple, one-dimensional scales such as the Rating Scale Mental Effort can assess the experienced mental workload (and the effort invested). The popularity of self-reports may also be due to the ease and low cost of the technique. However, when assessing mental workload, self-reports are not enough (De Waard and Lewis-Evans, 2014; Matthews et al., 2019). For example, to know whether performance was protected by the investment of mental effort, one needs some objective measure of performance, in addition to the self-reported measure of workload.

Self-reports are also useful for assessing driver state: fatigue and sleepiness can be scored on a validated scale such as the Karolinska Sleepiness Scale. But again, just as with mental workload, a self-report of driver state is not enough, nor is it always accurate. Simply put, if drivers were able to evaluate their state correctly, why would accidents with drivers who fall asleep still happen? Another disadvantage of self-reports is timing: either normal behavior needs to be interrupted to obtain a rating, or ratings have to be given in retrospect after completing a (part of the) drive, which means they may be impacted by memory decay.

Figure 2 Example of a psychophysiological measure. Average heart rate in beats/minute (left axis) and variability of heart rate (HR Variability) in the 0.10 Hz frequency band (right axis, Ln-transformed, unit Ln^2). The averaged values of 24 participants performing a merge maneuvers (at $t = 0$ s) in their own car are depicted. On the x -axis, time is depicted in seconds. In general heart rate increases while variability decreases with increased mental effort.

Physiology

The ability to register how the driver responds physically to certain situations makes psychophysiological measures very attractive as indicators of mental workload or driver state (Hughes et al., 2019; Mehler et al., 2012). There is a broad range of measures, some requiring more advanced equipment than others. Heart rate and heart rate variability are relatively easy to assess, even though for the latter higher measurement accuracy is required. Average heart rate alone can reflect increased effort investment and reduced driver state. For driver state, measures that reflect Central Nervous System activity, such as EEG (electroencephalogram), are more accurate, but they are also more intrusive than Peripheral Nervous System activity measures, such as electro dermal activity and heart rate.

Some of these measures give the impression that they are objective and reveal the truth. In practice, this is not the case. These measures simply reflect how we respond to situations after interpreting them, and in that sense could just as well be called subjective measures. Apart from the fact that some require almost esoteric knowledge to administer and interpret them, a major disadvantage is that their reliability can be severely impacted by artifacts (disturbances that are not part of the physiological signal of interest, occurring as a result of movement, for example). On the other hand, an advantage of these measures is that many of them can be collected and interpreted continuously, so they can potentially be used in (partly) self-driving cars for monitoring purposes.

Fig. 2 illustrates how heart rate can reflect the performance of an effortful maneuver in traffic. A relatively high heart rate from the beginning reflects mental preparation; the heart rate variability is reduced in this condition, signifying higher mental effort. After the effortful maneuver, the heart rate slows down and the variability increases—both reflect less mental effort as the driving circumstances become less demanding.

Interpretation of Measures

Different measures can reflect different processes and driver states. For several reasons, it is important not to focus on one measure only. Different measures can and will diverge, which actually helps to interpret how the driver handled the situation. For example, the previously mentioned protection of performance should, by definition, show no primary task performance deterioration, while other measures such as self-reports or physiological measures can indicate an increase in mental workload. Furthermore, not all measures are equally sensitive or sensitive to the same task demands. For example, self-reports reflect investment of extra effort in conditions of both state- and task-related effort, while a physiological measure, such as heart rate variability, is only sensitive to task-related effort.

One would expect performance in the central area of Fig. 1 to be optimal; however, there are conditions related to self-regulation which could further improve performance. For example, while driving on a wide highway lane there is no need to minimize SDLP (swerve as little as possible)—however, with increased task demands drivers may actually swerve less, improving performance as a result of being extra activated. This somewhat counter-intuitive finding should be kept in mind when interpreting data: drivers have a lot of freedom to regulate their behavior, not only with regard to performance, but also at higher levels, depending on the goals they set. Self-regulation can also lead to other changes in behavior: drivers may decide to avoid situations that increase attentional demands, deciding, for example, not to drive during adverse weather conditions or on unfamiliar roads. In terms of traffic safety this can be a positive effect for drivers with limited experience (graduated licensing) and may extend mobility for drivers who suffer from mild cognitive impairment.

Conclusion

Driver state and workload demand can both affect performance, and thus driving safety. New advanced in-car systems that support, or even take over, parts of the driving task have the potential to make driving safer, but at the same time they affect driver workload and driver state. Before fully automated driving is realized, increasing levels of partial automation will continue to transform the driving task into a monotonous supervisory task, which can lead to driver underload. This state is obviously suboptimal and can jeopardize safety. On the other hand, as vehicles become more automated, if the driver needs to monitor many systems which are not well integrated, then the opposite effect—driver overload—could occur. To avoid both undesirable conditions, automation at all levels must be designed to provide optimal task demands, and this requirement must be tested prior to its introduction on the road. One promising way to optimize task demand is to dynamically adapt the driver's tasks on the basis of driver state and adaptive automation. In conditions where demands are high and overload is possible, tasks are taken over by automation to reduce the mental workload. In conditions where demands are low and underload lurks, tasks are handed back to the driver. In this way, the driver's performance is kept at the top of the inverted U in [Fig. 1](#).

Importantly, we should take multiple measures when we evaluate mental workload in experimental or naturalistic conditions, such as when investigating the effect of adaptive automation on mental workload ([Van Gent et al., 2018](#)). There is no single measure that reflects mental workload over the full range. Each measure is sensitive and not to all changes in task demand; the patterns that emerge from performance measures, self-reports (in experimental studies), and physiological parameters can provide a good indication of driver's mental workload and state.

The Use of Drugs and the Risk of Road Accident: General Issues

Everybody knows that consuming alcohol before driving increases the risk of being involved in a road accident. The more you drink, the higher the risk. Does this also apply to drugs? One can easily think that the use of some drugs would increase accident risk, for example, drugs that make you sleepy, produce hallucinations, or otherwise influence cognitive functions. It has, however, proved considerably more difficult to estimate the relationship between drug use and accident risk, than to estimate the corresponding relationship for alcohol. This article reviews current knowledge regarding the relationship between drug use in drivers of motor vehicles and their risk of accident involvement (Elvik, 2013, 2015, 2018). The article does not deal with the risk of injury associated with drug use among pedestrians or cyclists, as there are almost no studies of it. The article has two main sections. The first section reviews some general issues concerning the quality of knowledge. The second section summarizes, for fourteen drugs, what is known about the relationship between use of them and the risk of involvement in a road accident.

Several general issues related to the quality and reliability of knowledge regarding the association between driver drug use and accident involvement arise when trying to summarize the current knowledge. Some of the issues arise in primary studies; others arise when trying to summarize evidence from several studies. The principal issues of concern are as follows:

1. The determination of the dose taken of a drug and the level of impairment caused by it while driving.
2. Controlling for other factors influencing accident risk in addition to the drug of primary interest.
3. How best to summarize the relationship between drug use and accident involvement, that is, either as a point estimate or as a functional relationship.
4. How to test and adjust for the potential presence of publication bias in studies of driver drug use and accident involvement.
5. How to assess study quality and its relationship to estimate the risk of accident involvement associated with drug use.

The first two of these issues arise in primary studies, the other three when summarizing the results of a set of studies.

Determining Dose of Drug

Most of the studies of the relationship between driver drug use and accident involvement are either case-control studies or culpability studies. In case-control studies, a case sample, usually injured drivers treated at hospitals, is compared to a control sample, often drivers stopped in roadside surveys. In this study design, it may be challenging to collect high quality data on the dose of drugs present in the body for both case and control drivers. Blood samples provide the best basis for determining the dose. Taking a blood sample is an invasive procedure, not easily administered roadside to drivers, most of whom are likely to be negative for drugs. To circumvent this difficulty, some studies have used less reliable sources of data to determine the dose of drugs, such as samples of saliva or urine, prescribed dose and self-reported use.

In culpability studies, drivers involved in accidents and judged to be at fault are compared to drivers involved in accidents judged not to be at fault. If both groups of drivers are recruited at medical facilities, it may be easier to collect high-quality data on drug use than in roadside surveys. There are, however, other problems in culpability studies, principally concerning the validity of assuming that drivers not-at-fault are representative of drivers in general and the interpretation of the estimator of risk usually applied in these studies (Røgeberg, 2019).

As a result of these problems, only a few of the studies of the relationship between driver drug use and accident involvement rely on high-quality data regarding drug use. In most studies, there is no precise information on the dose taken or when it was taken.

Thus, in some studies, it cannot be ruled out at that, at the time of the accident, the drug had been completely metabolized and become inactive. This is a major source of uncertainty in the results presented in the next section.

Controlling for Confounding Factors

The risk of becoming involved in a road accident depends on a host of factors. Drug use is just one of them. In order to correctly estimate the contribution to risk attributable to drug use, a study should, ideally speaking, control for all other factors that are known to influence accident risk. In practice, that is not possible. Studies vary considerably with respect to how many, and which, potentially confounding factors they control for when estimating the risk associated with a specific drug.

Easily observable factors, such as age and gender are controlled for in many studies. Quite a few studies also control for the use of other drugs than the one, which is of principal interest in the study. However, a minority of studies control for annual driving distance. This is a serious omission, as accident risk is known to be inversely related to annual driving distance (Elvik, 2011). One can easily imagine that drivers who depend on regular use of prescription drugs limit their driving, especially if the drug has side effects, which the driver notices while driving. Thus, an unbiased comparison requires that drivers using drugs should drive the same annual distance as drivers not taking drugs (either by study design or by statistical control for driving distance).

The absence of control for driving distance in most studies of the risk of accident involvement associated with drugs is a source of uncertainty in the results presented in the next section. More generally, a negative relationship has often been found between how well a study controls for confounding factors and the estimate of risk associated with a drug. The better the control for confounding factors, the lower the increase in risk attributed to the drug.

Choice of Estimator of Risk

Traditionally, the most common way of presenting the risk associated with a certain risk factor has been as a point estimate, for example, this risk factor is associated with an increase of 50% in the chance of accident involvement. For at least two reasons, presenting the risk associated with drug use as a point estimate can be uninformative. First, it seems reasonable to expect the effect of a drug to depend on the dose taken. Risk would then take the form of a dose–response curve, similar to the curves reported for blood alcohol concentration and the risk of accident involvement.

Second, it has been found, at least for illicit drugs, that there is an interaction between how common uses of a drug is in the normal population of drivers and the increase in risk associated with use of the drug. There tends to be a negative relationship: the higher the percentage of drivers in normal traffic using a drug, the lower the increase in risk associated with it. Fig. 1 gives an example.

The point estimate of risk of fatal injury associated with the use of cannabis—for the studies included in Fig. 1—is 1.37, or 37% increase in the risk. This is indicated by the horizontal line in Fig. 1. Individual estimates of risk are, however, widely and asymmetrically dispersed around the weighted mean estimate of risk. Most estimates of risk applying to studies where less than

Figure 1 Point estimate of odds ratio of involvement in a fatal accident associated with the use of cannabis and functional relationship between share of control group drivers testing positive for cannabis and odds ratio of accident involvement.

10% of control group drivers tested positive for cannabis are located above the weighted mean estimate of risk (Elvik, 2018). All estimates based on studies where more than 10% of control group drivers tested positive for cannabis are located below the weighted mean estimate of risk. A curve has been fitted to the estimates. Although there is large variation in estimates around the curve, one could argue that it is a more informative summary of results than the single point estimate of risk.

Unfortunately, a curve as shown in Fig. 1 can arise in many ways. It can be a statistical artifact, but may also represent a real relationship. Many different interpretations are possible. Thus, when a negative relationship is found between the prevalence of use of a drug in normal traffic and the risk associated with it, this represents an additional source of uncertainty in knowledge, as it is rarely possible to determine why there is such a relationship.

Publication Bias

Publication bias denotes a tendency not to publish studies if the findings are not statistically significant or go in the opposite direction of what researchers expected and are therefore regarded as difficult to interpret or explain. A number of statistical techniques have been developed to probe for the potential presence of publication bias in a set of studies and to determine its magnitude. An informative technique is the trim-and-fill method. It is based on detecting asymmetry in the distribution of results plotted in a funnel plot.

A funnel plot is a scatter diagram of results. The abscissa shows the estimate of risk, the ordinate shows an indicator of the precision of the estimate, for example, its standard error. Standard error is usually plotted inversely, that is, the smallest standard errors are on top of the ordinate. Fig. 2 shows a funnel plot of estimates of the risk of becoming involved in a property-damage-only accident associated with the use of cannabis.

There were 19 estimates of risk, that is, the circular and triangular data points in Fig. 2. These were, as can be seen, very asymmetrically distributed and located far from the ordinate, suggesting publication bias with respect to both, the sign and magnitude of risk. Trim-and-fill trimmed away 15 of the 19 data points. When the mirror images of these data points are inserted, the plot becomes symmetric around the trimmed mean, but still has a hollow core. This is an example suggesting extreme publication bias.

Obviously, no statistical method provides direct evidence of publication bias. Such evidence can only be obtained by locating unpublished studies and comparing their results to published studies. The statistical methods are indicative only. Nevertheless, it is not difficult to imagine that publication bias could arise in studies of the risk of road accident associated with the use of drugs. Many researchers may expect the use of drugs to be associated with an increase in risk and may be puzzled and unable to explain an opposite finding. They may then choose to bury the study rather than try to get it published.

Figure 2 Trim-and-fill analysis to detect and correct for publication bias in estimates of the odds of involvement in property-damage-only accidents associated with the use of cannabis.

Figure 3 Relationship between study quality score and estimate of risk of accident involvement associated with the use of antidepressant drugs.

Study Quality Assessment

Study quality is a concept that does not have a standard definition and that escapes precise measurement (Greenland, 1994). However, nearly all researchers agree that studies vary in quality and that findings may be related to study quality.

Can we place equal trust in the findings of a study relying on self-reports only and not controlling for any confounding factors, as in a well-controlled study containing precise data on the dose taken of a drug that was still active during driving? Most researchers would say “no.”

Any attempt to quantify study quality contains an element of arbitrariness. An explicit and numerical scale for study quality assessment, explained in sufficient detail to be replicable, may still provide useful information. One should be reluctant to interpret numerical scores for study quality as anything more than an ordinal scale. Such a scale is nevertheless sufficient to determine, if there is any relationship between study quality and study findings. Fig. 3 shows an example.

Fig. 3 shows the relationship between quality score, on a scale ranging from 0 to 1, and estimates of the risk associated with the use of antidepressant drugs. A regression line has been fitted to the data points. The regression line is highly uncertain, as indicated by the dashed lines based on the lower and upper 95% values of the intercept and slope of the regression line.

Despite the large uncertainty, there is a systematic relationship between study quality score and estimate of risk. The higher the quality score, the lower the estimate of risk. The dispersion of estimates of risk also diminishes as study quality improves. For studies scoring 0.65, the range of estimates of risk spans from 1.61 to 0.59. For studies scoring less than 0.30, the range goes from 4.00 to 0.67. It is worth noting that the best studies scored 0.65, whereas a “perfect” study according to this scale would score 1. Thus, even the best studies have shortcomings.

Risks of Road Accident Associated With Illicit and Prescription Drugs

Drugs were included if at least three estimates of the risk of road accident associated with use of them could be found. A total of fourteen drugs met this requirement. Four of the drugs are principally used as illicit recreational drugs. Ten are prescription drugs used in the treatment of diseases. It should be noted, however, that some drugs are used both illicitly and legally. Thus, opiates are both used illegally and in analgesics for treatment of pain. Cannabis is also used both as an illicit and a prescription drug. There is a trend to legalize the recreational use of cannabis. Cannabis is by far the most commonly used drug of those that have been classified as illicit.

Table 1 describes the effects or intended use of the drugs (Marillier and Verstraete, 2019). If we make a broad distinction between stimulants and sedatives, two of the illicit drugs are stimulants (amphetamine and cocaine), two are sedatives (cannabis and opiates). The prescription drugs are used in the treatment of pain, asthma, depression, allergies, inflammations, anxiety, insomnia, diabetes, withdrawal symptoms in opiate addicts, and bacterial infections.

Table 1 List of drugs included and principal use and effects of the drugs

Drug	Effects of drug or intended use of drug
<i>Illicit</i>	
Amphetamines	A family of stimulants used both as an illicit recreational drug and as a prescription drug in the treatment of attention deficit hyperactivity disorder (ADHD). Amphetamine induces fatigue resistance and increased muscle strength. At high doses, it may impair cognitive function.
Cannabis	Drug made from a plant and used both as an illicit recreational drug and as a prescription drug. In recreational use, smoking it like a form of tobacco is common. It is a sedative. In medical use, cannabis can be used to reduce nausea and treat pain and muscle spasms.
Cocaine	Cocaine is a substance found in the coca plant. It is an illicit psychoactive drug that may cause an intense feeling of happiness or agitation. It is highly addictive, because it increases the concentration of neurotransmitters associated with reward in the brain.
Opiates	Opiates are drugs extracted from the opium plant. They are used both as an illicit recreational drug and as a prescription drug in medicine. Most opiates are sedatives. Morphine is the most common medical drug in the opiate family. It is used to reduce pain.
<i>Prescription</i>	
Analgesics	Prescription drugs used to reduce pain. Some of these drugs are opiates.
Anti-asthmatics	Prescription drugs used to treat asthma. The drugs do not cure the disease, but act to relieve the symptoms.
Anti-depressants	Prescription drugs used to treat depression. The drugs may also be used to treat anxiety disorders and some forms of chronic pain.
Anti-histamines	Drugs (over the counter or prescription) used to treat allergies. Some anti-histamines are sedative and can induce sleepiness.
Anti-inflammatory drugs	Prescriptions drugs used to treat inflammations. Some of the drugs also reduce pain.
Benzodiazepines	A large family of prescription drugs with various uses, including as a tranquilizer, to reduce anxiety, insomnia, and muscle spasms.
Insulin	Prescription drug used to treat diabetes. It replaces insulin produced by the pancreas.
Methadone	Prescription drug belonging to the opiate family, used in maintenance therapy for addicts to opiates. Maintenance means it reduces withdrawal symptoms from cessation of opium abuse.
Penicillin	A prescription antibiotic drug used to treat infections caused by bacteria. Excessive use may cause bacteria to develop resistance, which means that the drug no longer kills them.
Zopiclone	Prescription drug use to treat insomnia; a sleeping pill.

Table 2 Summary estimates of the risk of road accident associated with the use of drugs (odds ratios)

Drug	<i>Estimates of odds ratio for accident involvement—95% confidence interval in parentheses—number of studies in parentheses</i>		
	<i>Fatal accidents</i>	<i>Injury accidents</i>	<i>Property-damage-only accidents</i>
Amphetamines	5.70 (3.27; 9.95) (13)	8.98 (3.44; 23.40) (4)	8.67 (3.23; 23.33) (1)
Cannabis	1.39 (1.26; 1.54) (32)	1.62 (1.22; 2.16) (22)	1.43 (1.26; 1.63) (19)
Cocaine	2.91 (1.81; 4.67) (7)	1.59 (1.06; 2.38) (5)	1.52 (1.02; 2.26) (5)
Opiates	2.03 (1.34; 3.09) (10)	1.98 (1.55; 2.54) (20)	4.76 (2.10; 10.80) (5)
Analgesics	2.35 (1.42; 3.89) (8)	1.78 (1.35; 2.36) (17)	
Anti-asthmatics		1.33 (1.09; 1.62) (6)	
Anti-depressants		1.28 (1.07; 1.52) (25)	1.28 (0.90; 1.80) (5)
Anti-histamines	0.69 (0.18; 2.63) (2)	1.12 (1.02; 1.22) (7)	
Anti-inflammatories		1.38 (1.22; 1.56) (5)	1.53 (1.17; 2.01) (4)
Benzodiazepines	3.26 (2.30; 4.62) (10)	1.65 (1.49; 1.82) (51)	1.36 (1.04; 1.76) (4)
Insulin		1.14 (0.84; 1.54) (4)	1.01 (0.59; 1.74) (2)
Methadone		2.08 (1.47; 2.95) (3)	
Penicillin		1.12 (0.91; 1.39) (5)	
Zopiclone	2.31 (1.13; 4.70) (2)	1.42 (0.87; 2.31) (4)	4.00 (1.31; 12.21) (1)

Estimates of the odds ratio of accident involvement, which closely approximates the relative risk of accident involvement associated with the use of the drugs, are presented in **Table 2**. A distinction was made between three levels of accident severity: fatal accidents, injury accidents, and property-damage-only accidents. The reason for making this distinction was to assess whether there is a severity gradient in the risk associated with the use of drugs, analogous to that found for alcohol. Alcohol dramatically increases the risk of fatal accident, is associated with a smaller increase in the risk of injury accident and an even smaller increase in the risk of property-damage-only accidents.

Illicit Drugs

All illicit drugs included in this review have been found to increase the risk of accident, at all levels of accident severity. The increase in risk is statistically significant at the 5% level in all cases, although some confidence intervals are very wide.

The largest increase in risk is found for amphetamine. In general, relative risks do not show any clear severity gradient, possibly except for cocaine. The largest number of studies refer to cannabis, 73 in total. For three of the illicit drugs, amphetamine, cannabis and opiates, a negative relationship is found between the share of drivers in normal traffic testing positive for the drugs and the risk associated with them. For cocaine, there were too few results to test for such a relationship.

In most cases, estimates of risk associated with illicit drugs had a negative relationship to the number of potential confounding factors controlled for in a study: the more confounding factors controlled for, the lower the estimate of risk.

The consistency of evidence can be assessed by examining whether all estimates of risk indicate an increase, or whether some estimates indicate a decrease in risk. There were 17 estimates of the risk associated with the use of amphetamine. All indicated an increase in risk. For cannabis, 58 estimates indicated an increase in risk, 15 indicate a decrease. For cocaine, there were 15 estimates indicating an increase in risk, 2 indicating the opposite. Of the 31 estimates of the risk associated with the use of opiates, 27 indicated an increase in risk and 4 indicated a decrease.

Estimates of risk vary substantially for all illicit drugs. The variation in estimates of risk is substantially larger than sampling variation alone can explain. Systematic between-study variation in estimates of risk typically constitutes two-thirds of the total variation in estimates of risk, the remaining third being random sampling variation. Sources of the variation in estimates of risk are only partly known.

Prescription Drugs

Estimates of risk were found for a total of 10 prescription drugs. Evidence is less complete than for illicit drugs. Estimates of the risk of an injury accident are available for all prescription drugs. No estimates of the risk of fatal accident were found for anti-asthmatics, anti-depressants, anti-inflammatories, insulin, methadone, and penicillin. No estimates of the risk of becoming involved in a property-damage-only accident were found for analgesics, anti-asthmatics, anti-histamines, methadone and penicillin.

The increase in the risk of injury accident associated with prescription drugs is modest and not statistically significant at the 5% level in all cases. The highest risk is associated with methadone, but there are only three studies and the mean estimate of risk is highly uncertain. A severity gradient in risk is found for benzodiazepines. A total of 65 estimates of risk were identified for benzodiazepines, close to the 73 estimates found for cannabis. For most other prescription drugs, there are few estimates of the risk of road accident associated with their use.

Testing for a relationship between the share of drivers in normal traffic testing positive for a drug and the risk associated with the drug was only possible for opioid analgesics. A negative relationship was found: the larger the share of drivers in normal traffic testing positive for the drug, the lower the increase in risk associated with it.

Anti-histamines appear to be protective with respect to the risk of fatal accident. A protective association has only been found for anti-histamines that are not sedative and only one study (of the two that were found) has found a protective effect.

For most prescription drugs, there are few studies of the risk associated with them. It has therefore in most cases not been possible to test if estimates of risk are related to how well a study controlled for confounding factors. Negative relationships were found for anti-depressants and for the association between benzodiazepines and the risk of injury accident; meaning that the more potentially confounding factors a study controlled for, the lower were estimates of risk. For the association between benzodiazepines and the risk of fatal accident, a positive relationship was found: the better controlled studies indicated a larger increase in risk than the more poorly controlled studies.

Estimates of the risk of road accident associated with the use of prescription drugs are less consistent than those for illicit drugs. Thus, as an example 9 out of 30 estimates for anti-depressants indicate a decrease in risk. Two of six estimates for insulin indicate a decrease in risk. For the most widely studied class of drugs, benzodiazepines, 7 out of 65 estimates of risk indicate a decrease, the other 58 indicate an increase of risk.

There is large variation in estimates of risk, although somewhat smaller than for illicit drugs. The share of systematic between-study variation in estimates of risk is typically around 45%, but ranges from 0% to 95%. Little is known about why estimates of risk vary between studies.

Concluding Comments

The risk of road accident associated with the use of drugs is poorly known. On balance, the evidence suggests that use of illicit or prescription drugs is associated with an increased risk of accident involvement. The increase in risk associated with drugs appears to be greater for illicit drugs than for prescription drugs. On the other hand, prescription drugs are more widely used than illicit drugs and may therefore, despite the moderate increase in risk associated with them, contribute more to the population attributable risk associated with drug use than the use of illicit drugs.

There are many sources of uncertainty in the estimates of risk presented in this article. The most important sources of uncertainty are as follows:

1. Most studies have no precise information about the dose taken of a drug. Very few studies have been able to test for a dose-response relationship between the dose taken of a drug and the size of the increase in risk. This means that a key criterion for assessing the causality of the statistical associations found is largely unknown.

2. Most studies do not control for a very important potentially confounding factor, annual driving distance. It is unlikely that regular users of illicit or prescription drugs drive the same distance per year as nonusers of drugs.
3. There is evidence of a negative relationship between the share of drivers in normal traffic testing positive for a drug and the risk associated with use of the drug. Although such a relationship can have many reasons, it casts doubt on how informative it is to summarize the risk by means of a point estimate, rather than a curve showing risk as a function of the share of traffic exposed to a drug.
4. Most tests for publication bias suggest that there is publication bias. If the results of these tests are taken at face value, they imply that estimates of risk are considerably exaggerated for many drugs. Thus, to give some examples, the estimate of risk adjusted for publication bias was 2.74 for the risk of fatal accident associated with use of amphetamine; the crude estimate was 5.70. Similarly, the crude estimate for injury accidents for benzodiazepines was 1.65; the adjusted was 1.18. The corresponding estimates for the risk of injury accidents associated with analgesics were 1.78 and 1.01.
5. Estimates of risk vary considerably for all drugs. Reasons for the variation are largely unknown. Explanations can be either methodological, that is, associated with weaknesses of the studies, or substantive, that is, pointing out why drugs increase risk more in some groups (e.g., novel users of the drug) than in others. Considering the generally poor quality of studies, the presumption that methodological explanations of the variation in estimates of risk dominate must be favored.

To conclude: It is more likely that the use of drugs increases the risk of accident than the opposite. Causality of the relationship has not been established.

Children's Traffic Education

Children's traffic education is primarily aimed at improving the safety of all road users. In the course of time, the concept of children's traffic education has expanded to also include education toward safe mobility, which includes the safe utilization of public transport and the choice of a transportation mode. It is mainly provided at kindergartens and primary and middle schools, exceptionally at secondary schools. This systematic implementation reflects the practical aspect, as the target group of children, unlike that of drivers, can be reached easily. The benefit of children's school-based traffic education is its secondary impact; it plays a significant role in building children's and young people's hierarchy of values, as well as having the potential to shape the attitudes of all prospective road users.

In specific terms, children's traffic education encompasses four major domains:

- Education toward mobility as education toward safety.
- Education toward mobility as a form of social education (raising young people's awareness about vulnerable road users and developing their empathy, willingness to help others, responsibility, thoughtfulness, and sense of partnership).
- Education toward mobility as environmental education (intended to raise children's awareness about environmental issues related to motor traffic and encourage them to behave in an environmentally friendly manner).
- Education toward mobility as health education (intended to help children recognize unhealthy factors and promote measures to alleviate them, e.g., the choice of a good means of transport on their way to school).

The last of the domains includes first aid education. This is a very important aspect, as road accidents in many countries are the most frequent cause of death among people below 25 years of age. It should be noted at this point that children as young as six are capable of providing effective first aid.

However, children's traffic education cannot rely on school only. A significant part of it takes place within the family, on an informal basis. From their early years, children learn whether breaking rules or aggressive or violent behavior at the wheel are "common traffic-related predicaments" or something inappropriate. Road use-related behavior is a type of habitual behavior, which children adopt once they begin to watch the world from their car seats. Children tend to internalize the behavioral models of their parents and significant others from a very young age and incorporate them into their future behavior portfolio. For this reason, the focus on children, even at the informal level, is a key element of traffic education.

Driving Education and Testing

Motorized vehicles, whether they are cars, motorbikes, or lorries, are complex machines which are not very easy to operate and are potentially very dangerous to the drivers themselves and also to others in their vicinity. Shortly after the invention of the motor car, it became an increasingly popular means of transportation, which also meant that these vehicles caused numbers of injuries and deaths. Very soon, it became evident that drivers should be registered and educated in order to reverse the negative effects of driving. Since then, governments and local authorities have granted driver's licenses, regulated driver education, and enforced the traffic rules.

A driver should not only be able to drive a car and maintain it but also drive the vehicle in a safe manner. Driver training focuses on teaching skills, which mainly support the goal of providing learners with skills that help them to increase their mobility, while, at the same time, focusing on traffic safety. Countries and states differ in their requirements for mandatory driver education. In order to

gain a driver's license, an aspiring driver undergoes the obligatory training and then has to pass exams—both theoretical and practical. Usually, the education is composed of theoretical lessons and practical driving training. Often, the theoretical lessons, or at least a certain number of them, must precede the driving training and they are not always compulsory. Theory, which includes learning the road code, traffic signs, and in some jurisdictions also car maintenance, can be taught in various forms: lectures in driving school classrooms, online courses, or self-study of books and other materials that are provided. Instructional videos can be shown and sometimes a computer is used. Once the theoretical part of the training is completed, sometimes a theory test follows, and if the learner is successful, it allows them to proceed to driving lessons.

Driving schools sometimes let their students train first on driving simulators, which can also be a mandatory part of the training. Practical driving lessons are taught one-on-one in cars fitted with dual controls that allow the instructor to take control over the vehicle, if needed while the learner sits behind the wheel. The instructor supervises the learner's driving and monitors possible mistakes while giving instructions and corrections. The lessons often start in easier places such as tracks or car parks and progress to more difficult locations, such as city traffic and highways. The number of hours spent on certain types of roads is sometimes established by law and includes not only roads, such as highways or country roads, but also driving in specific conditions, such as nighttime driving. Learners are taught to operate a vehicle and sometimes to use procedures (e.g., MISS for changing lanes—mirror, indication, shoulder check, steering). They learn a number of essentials which they must automatize, from adjusting their mirrors and seats and checking their blind spots and moving on to forward and reverse driving, signaling, parallel or bay parking, emergency stops, three-point turns, passing, changing lanes, and driving at intersections. Once they have attended the required number of driving lessons or, in some countries, when they feel confident about their driving skills, they proceed to final testing. To obtain a driver's license, applicants in some countries must take a theoretical exam, which is typically a multiple-choice test. Learners worldwide finish their training with a practical driving test, in which the examiner usually gives basic instructions, requests certain learned actions (e.g., emergency stop or bay parking) to be performed, observes what mistakes are made and how serious they are, and decides whether the applicants are good enough drivers to get their driver's license.

There are great differences in mandatory driver education worldwide; in some cases the system can be more complex, such as graduated licensing or required specialized lessons, while in other cases only the final test is required. In most countries, one can start driving a car unsupervised at the age of 18 years, though some countries allow even younger teenagers, even as young as 14 years, to drive. Driving lessons with an instructor can take 10–40 h in some countries, but in some places it can be as little as six or even none at all—passing the exam alone suffices. In some countries, a first aid course is also a part of the mandatory education. This training aims at reducing the damage to health and loss of life in the event of a traffic accident. Drivers also typically learn to drive only either an automatic or manual car, depending on what is locally widespread, and when relocating abroad, they might not be allowed to drive a different type of vehicle or damage the vehicle by incorrect usage.

Problematically Taught Skills

Driving is a complex activity that assumes a range of skills, experience, personality prerequisites, and motivational traits. Although the most appropriate solution for specific traffic situations is the possession of basic vehicle control skills, research has shown that for long-term safe management having only those skills is not enough (Mayhew and Simpson, 2002). Safe driving is an activity that requires particular insight and self-regulation on the part of the driver—driving is a “self-paced task.” It is up to the driver (his or her decisions and behavior) to choose a safe driving style.

Modern research in traffic psychology refers not only to the performance characteristics of drivers, but also to their personal characteristics and motivational factors. Therefore, what is assessed is not only what the driver is able to do (skills), but also what the driver intends to do (motivation and personality factors).

By the time the learners pass their final test, they have merely learnt the basics of driving. Given that their practical training usually lasted for only a couple of dozen hours spread over several months, they have not had the chance to truly master this skill. It takes thousands of kilometers driven to become a confident driver, for a reason. Newly licensed drivers are sometimes obliged to visibly display a learner's plate with a large letter L or P on the rear and sometimes also the front of a car for a given period to indicate to other drivers to be more considerate around new drivers. Fresh drivers can also experience different behavior in traffic than what was taught and then adjust their own driving accordingly, simply learning by observation and then spreading those ways to others. Seeing somebody break a rule encourages others to do the same and normalizes a certain type of behavior. It is essential for drivers to learn good habits soon, as they are unlikely to change them later—in particular, those habits that are formed very early can be almost impossible to break, especially when there are few incentives to do so.

Driving is a multitasking activity, which requires us to use our focus and constantly shift it. While driving, we must simultaneously follow our chosen route, keep the vehicle moving at the intended speed, watch the traffic signs and the traffic, communicate our intentions to other drivers, and pay attention to what is going on, while also anticipating the moves of others. Within a matter of seconds one must execute a number of checks on one's surroundings. This series of activities become automatic by experience; however, adjusting never stops. A driver must accommodate his or her driving to the current conditions, including taking into account different weights of cars, the surface, the weather or his or her own tiredness. Drivers can learn this only by experience as these conditions change and simply cannot be taught.

People very often undergo driver education as soon as they legally can. The downside of this is that in young adulthood, youngsters are prone to risky behavior, to underestimating the risks, and to deliberately breaking the rules. This can be explained by

immaturity of the brain, which continues until the mid-twenties (Mayhew and Simpson, 2002). To address this problem, sometimes stricter rules apply to new drivers and some countries have introduced a graduated licensing system.

Training aims at teaching learners necessary skills, but it also easily leads to overconfidence (Hatakka et al., 2002). Most people consider themselves above-average drivers, which also makes them take more risks. Having undergone training convinces people that they have mastered certain skills, so more education can actually lead to less safe practices, which for example, happens in skid training (Mayhew and Simpson, 2002). To avoid this, instructors should let their students experience failure and demonstrate how little control drivers sometimes have over their vehicle and add discussion about the topic and experience (Peräaho et al., 2003).

One of the things typically overlooked in curricula is communication. Traffic is an organic structure and its smooth and safe functioning depends on the quality of the interaction of all its participants. When not alone in an area, one should use principles of defensive driving, anticipating the mistakes made by others, and driving safely, but when there are other people, it is necessary to let them know about our intended move and allow some buffer in case there is a lack of clarity. During training, signaling is taught but there are also individual differences in various situations, which are rather a matter of intuitive courtesy or reactions learnt by observation. Lack of communication or miscommunication of intentions can have fatal consequences.

Usually, when people are using a certain mode of transportation at any given moment, whether it involves walking, riding a bike, or driving a car, they become fully immersed in their role and although they may try to drive safely, others might not recognize their behavior as being safe. Some drivers have a lower sensitivity threshold and drive too close to others, but often people can at least know which actions on the part of others make them uncomfortable and recognize that they should not impose those on others; however, it is a bigger issue when there are people using different modes of transportation. People often do not realize that while the way they drive is completely acceptable to them, others may find it uncomfortable or dangerous. All sides see things from different perspectives and, immersed in their own world, how the other party might feel often does not even enter their mind. To empathize with people who use different forms of transport, people can try to put themselves in their shoes by simply trying to get around in a way they usually do not—by bike or on foot. Such an experience can make them live out the perceptions and emotions of those who they typically pass and become more kind to them.

Another notable fact is that roads often are not designed to encourage safe behavior. For example, straight and wide roads do not encourage safe speeds. And, even more alarming, traffic engineers assume when designing roads that a lane of a motorway will be able to safely carry well over 2000 vehicles per hour at high speed, say 120 km/h, even though drivers in driving schools are told that they at such speeds should have a minimum cushion of 3 seconds to the vehicle in front of them. A 3-second gap will lead to a capacity below 1200 vehicles per hour. And, if a driver tries to keep a 3-second gap, someone else will often enter into that gap.

Graduated Driver Licensing (GDL)

Teenagers and young drivers are more likely to be involved in a crash than any other age group. Car crashes are also the leading cause of death for teenagers. This trend led to the adoption of GDL by a number of big countries, such as most states of the United States and Australia (Shope, 2007). Graduated licensing is a system in which the learner must go through multiple stages before obtaining a full license. There are usually three stages, during which new drivers hold various kinds of provisional licenses, depending on which stage they are at. Each stage comes with certain restrictions, such as a prohibition on driving during night hours, exceeding a certain speed, driving unsupervised, transporting young passengers, or using a phone in any way while driving. These restrictions are based on the most risky factors for this age group. A number of rules apply during the entire process, but on entering a new learning stage with a more advanced type of license, some rules become freer. Drivers usually first take a theoretical test and in the last stage take a practical driving test, but meanwhile may have required hours to drive or additional tests to pass.

A traditional part of the system is the requirement to, at least at the beginning, drive only with a supervisor, a person who has held a full license for a given period. Supervisors sometimes completely replace instructors. The supervisor advises the learner driver and sometimes confirms in a logbook what drives were taken. In some countries, learners must drive a certain number of hours in the daytime and another number when it is dark. Each stage has a firmly set or minimum duration, so the entire process can sometimes take about three years to complete, unlike in traditional driving education systems which can take only months or even weeks to finish. Grading the licensing process in this way gives the learner time to learn good habits and to enter challenging conditions gradually, but it also signals to the driver that he or she is still learning and is not yet a ready, competent driver. Another important factor is delaying the time when a young person becomes a driver with full privileges (Mayhew and Simpson, 2002). This is very useful, given the inexperience and risky behavior that is typical for that age, and thanks to the fact that graduated licensing addresses specific problematic and risky behaviors, this system has proved successful in reducing the numbers of crashes involving young drivers (Shope, 2007).

Driver Education Framework

Driving education is traditionally taught with lecture-style instruction in which interaction happens only when the instructor corrects the learner's mistakes, but knowledge and skills alone do not ensure safe driving. A great number of factors which intuitively we might not even associate with driving (and which go beyond driving) in fact have an impact on the way we end up driving. There are many motives and invisible influences which determine this, such as role models, the desire to fit in and to impress others, a habit

of doing things at the last minute, and so on. Our overall motives and goals determine how we often unconsciously decide to act and yet they are not addressed in standard driver education. The GDE framework describes what influences how we drive and how to modulate each level in the education process for the best outcome. Each level affects other levels, but the highest, fourth level, called skills for life, has the greatest impact on driving. It includes goals, lifestyle, and tendencies and is established even before one starts one's driver education. Increasing the number of hours dedicated to skills training will not change how one drives unless motivation and goals are addressed because we choose our driving strategy according to our goals. Concerning the lower levels, level one describes how to maneuver the car as an independent vehicle, level two describes how to behave in traffic and in different conditions and how to manage communication with other drivers, for which we need to master the traffic code. The third level concerns individual trips and decisions regarding choosing the means of transport and location, but also when and how, for instance at what pace will we travel (Peräaho et al., 2003). To improve safety, we should not only equip learners with the necessary knowledge and train them in technical skills until they become automatized, but also aim to challenge their attitudes and perspectives (Shope, 2007). The problem is that even if there is a skill, if there is no will to practice safe driving, the skill will not help. One must be willing to practice what was taught. To achieve this, the instructor should take on the role of a tutor and realize that people are strongly influenced by their preferences, convictions, and habits, and so taking a driver's preferences into account is vital. We cannot teach by simply telling them, but should combine suitable experience with theory and engage the student to experiment and learn new perspectives. The tutor creates an engaging program, which includes exercises, feedback, self-evaluation, and group discussions, even including role play about various situations (Peräaho et al., 2003). People downplay the hazards and are constantly subjected to their biases, but discussions and evaluation from others and oneself help raise self-awareness, which is the key quality here. Drivers should learn to know their weaknesses and limitations but they should be able to learn to recognize them independently over their lifetime. The tutor must attempt to understand and respond to the learner's goals while providing stimulating content, which teaches lifelong skills of metacognition. At the moment, addressing the highest level is only rarely present and only in postlicense training, although such training brings positive outcomes (Peräaho et al., 2003).

Continuous Education and Training

A driving license for cars does not have an expiration date, so the majority of drivers undergo nonrecurring (one-off) education. Unless one seriously violates the traffic rules, or moves to a different continent, he or she does not undergo any retraining or retesting. This means that what was learnt at the beginning of one's driving career is not likely to change and people are not systematically taught about safe practices or changes in traffic rules, as well as in technologies. Most of the traffic code involves unchanging rules, but sometimes new rules are introduced, such as late merging. The only group of people who are definitely informed about changes are lawmakers, traffic professionals, and professional drivers, while most of society will only learn about them through media coverage, if at all. The problem is that the message does not reach all people and can be forgotten or ignored, and, moreover, the media can unintentionally spread misinformation.

Drivers could also benefit from learning about new technologies implemented in cars. They themselves might not use them but other drivers can adjust their driving to how the vehicle reacts. New systems, such as advanced driver-assistance systems, whether collision avoidance systems, intelligent speed adaptation, or lane assistance, alter driving and learning about them can help drivers understand what to expect from other vehicles. At the moment, drivers will mostly only learn about them, if reading specialized literature and only, if they are interested in the topic.

First Aid Training

Medical advances also modify good practices in first aid. As first aid training is attended only once or sometimes not at all, the driver will most probably not know how to respond in case of an emergency or simply forget it. Thorough training events attended at regular intervals once in a set number of years might improve knowledge and skills and teach up-to-date first aid strategies, and also serve as an opportunity to teach drivers about developments in the traffic law and similar areas which might affect traffic.

It is estimated by the Red Cross that first aid education has the potential to reduce the number of deaths resulting from road accidents by up to 10% and can also minimize the consequences of serious injuries. In addition, training in first aid can be highly effective in increasing drivers' prosocial behavior and serve as a preventive factor for risky behavior in traffic. A number of studies show that mandatory first aid courses as part of driving school significantly improve prospective drivers' knowledge and confidence. Nevertheless, neither willingness to provide first aid nor the frequency of its actual provision will increase without psychological aspects and strategies to overcome psychological barriers being incorporated in such courses.

Training for Senior Drivers

In widespread suburban areas, a private car is a necessary means of transport and giving up driving can result in a large negative impact on a person's quality of life. Thus, methods that enhance driving safety and prolong the mobility of elderly people are important.

Different studies have indicated that cognitive functioning has a significant effect on the driving safety of elderly people, both in healthy people and those with mild cognitive impairments. By focusing on this association between cognitive functioning and driving safety, many studies have introduced different types of cognitive training and investigated their transfer effects on driving safety and the maintenance of mobility. Driving is a skill that can, and should, be continually improved. Courses designed for senior drivers keep their knowledge about driving fresh and help them get the most out of their vehicle, while reducing the risk to themselves, their passengers, and others on the road. A comprehensive driving improvement course ensures that senior drivers have the most up-to-date driving techniques and understand the latest vehicle technologies.

Defensive and Eco-Driving Courses

Two of the most common types of further training courses for nonprofessional drivers focus on defensive and eco-driving. The concept of defensive driving emerged in the 1950s in the United States and is associated with the “Smith System of Defensive Driving.” Defensive driving courses are generally aimed at teaching a driving strategy, which assures a sufficient level of one’s own safety despite the effects of external factors. They consist of a theoretical and practical part. The theoretical part of the course usually covers topics such as the prevention of traffic accidents, the risks related to road traffic, the principles of defensive driving, the causes of risky situations and road accidents, and physiological and psychological limits. The practical part of the course generally involves on-road driving evaluation focusing on observation of the rules, correct driving technique, defensive driving strategy, and economical driving. In the course of time, the principles of defensive driving have been incorporated into driving school curricula and taught independently in defensive driving courses. The concept of defensive driving later became criticized to some extent. It was argued that defensive driving could make drivers engage in aggressive behavior or result in collision situations brought about by drivers asserting their need for their own safety and disregarding the context or other road users (e.g., keeping too much of a distance in heavy traffic) (Steinmetz, 2008). Finally, the term itself implies defense, that is, counteraction, which does not correspond with cooperative principles. The modern notion of defensive driving no longer involves passively aggressive elements. Rather it is based on the assumption that others may make mistakes, so one should not assume that others follow all rules all the time.

Courses in eco-driving became common in the 1990s, offered either independently or together with training in defensive driving. Courses promoting eco-driving principles involve teaching drivers how to behave in specific situations in which fuel (i.e., money), time, and the environment can be saved. Eco-driving courses are also sometimes associated with a new driving culture that highlights not only safety but also environmental aspects and the application of smart technologies. In addition, these courses respond to advances in car design (Barkenbus, 2010). Recent decades have seen dramatic improvements in technology and horsepower, while the majority of drivers have maintained their old driving styles. Eco-driving courses are thus an important component of sustainable mobility and energy-efficient car use.

Introduction

There is no standard definition of an “elderly” person, for example in most developed countries it is 60 years or more use, while for the United Nations it is 65 years or more; other definitions distinguish between being old and being elderly, with the latter indicating a degree of frailty. Age, like many other categories used in popular language, is socially constructed, and this in turn influences statistical categories. Regardless of the chosen category, population aging is occurring across the globe, and this, together with the decline in individual driving ability with age, is the basis for concerns about the safety risk that elderly drivers constitute to themselves, their passengers and other road users. At the same time, reliance on personal transport has increased in many countries, while use of alternative forms of transport by elderly people has declined. Beyond this basic picture, however, there are various levels of complexity that influence the safety of elderly drivers, including demographic, developmental, social, and behavioral factors. This entry gives a brief overview.

The Aging of the World and Some Gender Differences

For several decades high-income countries have noted that their population have been characterized by an increasing proportion of elderly people, as a result of lower birth rates and longer life expectancy. In some countries population have fallen. However, population aging is already a feature across all regions of the world, except Africa, and even Africa is projected to exhibit an increase in the proportion of elderly people across the region by 2050 (Fig. 1). Note that in Asia, which accounts for about 60% of the world’s population, the proportion aged 60 years and over will approximately double.

The implications of these changes for the road safety of elderly people, especially as drivers, vary by region. The greatest uptake in driving as countries are motorizing tends to be among people of working age, so that initially the proportion of elderly drivers is less than the proportion of elderly people. However, once licensed, drivers tend to maintain their license and continue driving as they age, so that the proportion of elderly people who drive increases progressively and draws close to the proportions observed among people of working age.

Driving varies by gender, with males being more likely to be licensed than females, sometimes by quite large amounts. The reasons relate to a range of factors including gendered division of labor, traditional gender roles (including religious and cultural traditions), income inequity, and the degree to which legislation and administration of driving is influenced by any of these factors. In Western countries, female uptake of licensing increased in the 1970s, however males still tend to drive more and be more likely to drive for employment purposes.

This gender difference in driving is important because population aging also differs by gender. Women consistently live longer than men, by about 5 years in high-income countries, and around 4 years in other countries (Table A.28, United Nations, 2019). Given marriage practices which mean that men are on average older than women at time of marriage for all countries (with the possible exception of Nauru), most married women will live several years after their husband dies and are therefore more likely to find themselves reliant on other people for transport or needing to become licensed themselves for the first time (King and Scott-Parker, 2017).

Ageing and Driving Performance

For road safety, the aging of the population is important because “normal aging” (an increasingly debated term) is associated with a decline in perceptual, cognitive, and physical abilities, as well as a decline in overall health. These changes have implications for crash risk and for crash severity.

Safe driving (i.e., lower crash risk) requires drivers to perceive the features of a constantly changing environment sufficiently well and focus on them, while aging is associated with declines in vision (especially night vision), hearing, and processing of sensory data. The driver must distinguish between relevant and irrelevant information once it has been perceived, predict likely outcomes of different motion/speed/direction combinations for one or more vehicles, and make sound decisions about safe courses of action, whereas aging is associated with declines in the ability to integrate information and make accurate decisions rapidly. Any decisions made by the driver must then be physically enacted through manipulation of the steering, acceleration, and braking functions, while aging is associated with declines in muscle strength, speed and precision of movement, and accuracy of proprioception. All of these age-related changes have been researched in laboratories, driving simulators, field studies, and (more recently) naturalistic driving studies. However, investigation of the crash risk associated with any particular effect of aging is methodologically challenging.

In addition, there is significant variability in the effects of aging from person to person, and there is a wide range of variability within any given age. *Fig. 2*, though not derived from a study on driving, gives an indication of the variability observed within people of a given age with respect to mental and physical capacity across a number of countries. The median scores remain within the range observed for young adults until the 90s are reached, where the sample size and that there is little difference between the worst performing individuals from the mid-50s on. The authors note that the trend in the mean does not match the trend for individuals, who may experience recoveries after declines. They also state that: “. . . for the population as a whole, the average reduction shown in this analysis was gradual. There was no age when people suddenly had less capacity and became ‘old’.” This has important and generally unappreciated policy implications that will be mentioned further.

Ageing and Injury Severity, and the Biases Involved in Focusing on Fatality Data

If a crash does occur, aging also contributes to greater injury severity. Ageing is associated with a loss of bone density and much slower healing, so that impact forces that lead to injury in younger people can be fatal in older people. This is most obvious when comparing the population rates at which people of different ages are killed or injured in traffic crashes (*Fig. 3*). Note that the different scales on the left and right axes of *Fig. 3* show that, up to the 50–59 years age group, there are about 55 injuries for each fatality, and the patterns are very similar, peaking for the 17–20 years age group and declining thereafter. For injuries, the rate continues to decline with age, which is consistent with a decrease in overall exposure (participation in traffic). However, from 60–69 years onward the fatality rate increases. Taken together with the decline in nonfatal injuries, this implies that while risk of injury in traffic crash decreases with age (at a population level), there is an increasing probability that the injury will be fatal from around 60–69 years.

These data came from an Australian crash database; while imperfect, the nonfatality data is reasonably reliably and comprehensive when compared to other countries. However, there is a tendency for media reports on road crash trends to focus on fatalities.

Figure 2 Range of scores on a composite of mental and physical capacities by age. Source: *Beard et al. (2015)*.

The fatality rates imply an increasing risk as people become older, consistent with expectations about how the effects of aging affect driving performance and other transport modes, but this is not borne out in injury data. Recent research from the same Australian state shows that all main forms of traffic exposure (as driver, passenger, or pedestrian) decline with age, so this decline in exposure is apparently sufficient to reduce the population rate of injury in a road crash for older people. Focusing on fatalities alone can provide a biased impression of the relationship between population aging and impact on road safety.

It is important to reiterate that *Fig. 3* is about population rates of fatality and injury, not the rate given exposure. The next section discusses mitigating factors like decreased exposure that lead to lower levels of older driver crash involvement than might be expected.

From Driving Performance to Crash Incidence—Mitigating and Exacerbating Factors

As explained earlier, an implication of population aging is that there will be a rise in fatalities as the proportion of drivers who are elderly increases, while the effects of aging on driving performance would be expected to increase the crash risk of older drivers, both of which imply that demographic change should lead to a significant road safety problem. In practice there has not been a marked change in crash involvement, a point that had been made by a number of prominent researchers over the past few decades.

However, as noted earlier, exposure in the form of miles/kilometers traveled decreases with age. When crash risk is calculated based on miles/kilometers traveled, it shows an increase in crash risk from 60 or 70 onward, even when the bias toward fatalities is taken into account. Further research has found that this is an oversimplified picture of road safety for elderly drivers that is distorted by an effect known as the “low mileage bias” (*Antin et al., 2017*). When older drivers are grouped according to how much driving they do in a year (their “mileage”), it is only the drivers with the lowest mileage that show an increase in crash risk per 100,000 km from around 60–70 years, with some studies showing that drivers in other mileage categories have a lower risk than all other drivers. Drivers who drive least are the high-risk drivers, and this group has been shown to be more likely to be frail, a term applied to older people who are more vulnerable to illness and injury, and in general terms are weaker, slower, and more prone to fatigue. Their impact on crash figures for elderly drivers is limited by their much lower mileage, and it is possible that they are more likely to give up driving voluntarily, or to be influenced to give up by doctors or family members.

Reduction of exposure by elderly drivers has been interpreted as an example of self-management of safety, reducing exposure to compensate for increased risk. For example, elderly drivers often state that they avoid driving situations such as peak hours and high-speed roads. However, it has been pointed out that this may have little to do with awareness of safety; instead, avoidance of peak hour traffic could be due to the combination of motivation to avoid frustration in traffic and flexibility in choice of when to drive. Similarly, avoidance of high-speed roads could be motivated by discomfort experienced when traveling at speed among other vehicles, since it is challenging to cope with the flow of information from the driving context at speed when a driver is older; the

Figure 3 Median road traffic casualty and fatality rates per 105 population by age category (years), Queensland, Australia 2001-2005 (casualty rate left axis, fatality rate right axis). Source: King et al. (2007).

easiest way to deal with too high flow of driving-relevant information is to slow down to reduce the flow. On the downside, it is common for drivers in general to regard the posted speed limit almost as a mandatory speed, and elderly drivers report intimidation by other drivers (such as tailgating) to pressure them to speed up. In both cases, elderly drivers report feeling discomfort while driving, and the psychological construct of discomfort has been found to have better value in explaining older driver preferences than safety compensation.

A related issue is that self-management by elderly drivers assumes that they are aware of their declining skills, able to make decisions about how to manage the issue, and able to successfully implement the decision (Hassan et al., 2015). Since people at all ages vary in their self-awareness and may be prone to optimism bias (thinking they are “better than average” when they are not), and since the cognitive declines associated with aging may affect self-awareness, deliberate self-management (as opposed to incidental self-management via avoidance of discomfort, for example) may not be common. A complicating factor is that the final step in self-management is to be able to change behavior, but this has a contextual aspect: for example, if an elderly driver lives alone in an area with poor transport options, they may not be able to give up driving or even to reduce it much. Some countries are highly car-dependent, and research has shown that even drivers who are aware that their abilities have declined feel unable to stop driving. This is common in urban areas where one would expect more transport options to be present, and is explained by the elderly drivers believing that there are other people (family or friends) who rely on them being able to drive. Interventions aimed at familiarizing elderly drivers with their transport options and encouraging self-directed change show only short-term improvement in knowledge and intention.

Road Infrastructure Implications of Crash Patterns Among Elderly Drivers

The higher likelihood of fatalities among older drivers involved in crashes has been mentioned. There are other crash patterns that provide insights of varying value. As driver age increases, drivers are more likely to be involved in intersection crashes, although it is unclear whether this is due to greater city/suburban driving (rather than high-speed roads), the low mileage bias (since short trips will occur in the more densely populated areas around drivers’ residences) or declining ability to deal with the decision processes required to negotiate intersections (gap judgment, prediction of vehicle speed and trajectory). More important, as driver age increases, the driver is more likely to be considered “at fault” in their intersection crash and in crashes in general. The other driver age group with higher than average “at fault” crashes is young drivers in their first few years of driving, and a comparison with young drivers reveal an interesting difference. For young drivers, “fault” is more likely to be assigned because of a deliberate illegal, unsafe act, such as speeding or drink driving; for older drivers, it is more likely to be assigned for errors of judgment or poor decisions (Rakotonirainy et al., 2012). This is consistent with what is known about the effects of aging and the processes of maturation among young drivers, and as noted below, it has implications for interventions to address older driver safety.

In the 1980s and 1990s, road authorities devoted resources to understanding the implications of these crash patterns for road infrastructure design and implementation, and developed guidelines for design and construction. These have tended to be absorbed into standards and guidelines generally, although there are still gaps. For example, research indicates that assumptions about the required minimum standards for road signage, in particular the distance at which a sign can be recognized, only hold for nonelderly drivers in general, and fail to take into account the poorer contrast sensitivity and acuity of elderly drivers at night.

The greater challenges experienced by elderly drivers at intersections and in gap judgment suggests that signalized intersections with fully controlled turns would be desirable, however this has implications for traffic flow that can take priority. Roundabouts can address both safety and traffic flow objectives, provided demand is not too skewed across approaches at peak times, although elderly drivers tend to feel uncomfortable on multilane roundabouts due to the merging and lane crossing involved. A related infrastructure consideration is that the much higher rates of intersection crashes among elderly drivers means that, if they strike a fixed object, it is much more likely to be a pole than a tree; however the approach to pole installation and protection in urban areas does not approach the issue from an elderly driver perspective.

Normal aging is associated with changes in vision including lower contrast sensitivity, which at night becomes important because the visual scene is mostly perceived as various shades of gray. Elderly drivers may not be able to see pedestrians in dark clothing until they are too close to react, and like most other drivers will tend to drive at a speed that does not allow sufficient time from the appearance of a hazard in the headlights to stop in time (Wood, 2020). In many places there is a lack of road lighting to compensate, and elderly drivers are also more sensitive to glare effects. In addition to normal aging effects on vision, elderly drivers have a greater incidence of visual conditions such as glaucoma and advanced retinal maculopathy. Cataracts (a progressive clouding of the lens in the eye) are arguably part of normal aging (since most people eventually develop cataracts) and leads to both reduced visual acuity and glare sensitivity, however cataract surgery reverses its effects (Wood, 2020).

Vehicle Safety Implications of Elderly Driver Crashes

The much higher proportion of crashes that result in fatality rather than nonfatal injury for elderly drivers suggests that the common vehicle occupant protection measures that mitigate severity risk among most drivers are not as effective for elderly drivers. A common injury among fatally injured drivers is thoracic trauma, where the standard seat belt design leads to forces on the thorax that can be fatal for elderly drivers because of lower bone density. Alternative seat belt designs have been developed, though their use is not widespread.

For social and economic reasons, elderly drivers do not update their vehicles frequently, so that the benefits of more advanced safety features are not passed on as quickly. Conversely, elderly drivers experience more difficulty in adapting to new design features such as advanced driver assistance systems (ADAS), which they find distracting.

A less commonly explored area is the degree to which proprioceptive feedback from the vehicle is detected and responded to by elderly drivers. There are many crashes where an elderly driver presses the accelerator instead of the brake and does not appear to understand what has happened and how to correct it. As proprioceptive sensitivity in the legs declines with age (Lacherez et al., 2014), it is possible that elderly drivers find it hard to correctly place their feet and to detect the differences in feedback from pedal vibration and response that distinguish the accelerator and brake. There are ways of changing this feedback, but this is not part of vehicle design. An alternative and interesting line of research downplays this issue in favor of neural changes, arguing that older people's executive functioning declines, such that their ability to override or change an incorrect decision is harmed (Makizako et al., 2018).

Overall cars are not generally designed with aging in mind. In the same way that there has been a growing appreciation that standard crash test dummies do not represent the injury response of children and women, it can be argued that they do not represent the vulnerability of elderly vehicle occupants. More relevant crash testing could lead to the development of standards that ensure a much higher level of safety for elderly occupants.

Licensing and Medical Approaches to Elderly Driver Safety

Elderly drivers involved in crashes are often depicted in the media as examples of people who should not be allowed to drive because they do not meet the minimum standard required, hence arguments are advanced that older drivers need regular testing and need to conform to a strict standard. However, there is limited evidence that regular (or even targeted) testing of older drivers is an effective way of addressing elderly driver safety (Ichikawa et al., 2020). This may reflect the influence of other factors, for example, there is evidence that elderly drivers who know their ability is declining decide voluntarily to not renew their license, and that family members may directly or indirectly (through the family doctor) encourage the elderly driver to stop driving. There are also variations across countries in licensing practices for elderly drivers and the role of training and assessment: in some countries (e.g., Japan) licensing interventions for elderly drivers appear to be effective.

Also common in the media is the representation of elderly drivers as a risk to others, whereas the data on fatal crashes shows that if an elderly driver is involved, they are probably the person killed.

Often licensing approaches to elderly driver safety incorporate medical assessment. Such assessments cover the effects of normal aging as well as the wide range of health problems that are more common (though not "normal") with aging. Many of these

conditions require medications that independently impair driving—although medication can also have beneficial effects on driving. The great diversity of conditions, medications, combinations of medications, and individual differences in response make it practically impossible to apply simple rules about driving restrictions, leading to a reliance in many countries on medical practitioners to make judgments about whether their elderly client can drive safely. However, in spite of the development of guidelines to assist them, many medical practitioners do not feel comfortable making these decisions.

Giving up Driving

Ultimately, anyone who lives long enough will eventually be unable to drive safely, though there is large variation in when that might occur. As a consequence, there are many programs aimed at facilitating a shift from driving to other forms of transport. Unfortunately, the evidence shows that when a driver reaches the point where they are unable to drive safely anymore, their capability to take public transport or walk is also considerably reduced (Liddle et al., 2014). There are more subtle social and personal issues as well, since giving up driving means ceding control over part of one's life, and could be an important part of one's identity (especially among males). The loss or reduction of opportunities to socialize face-to-face, or simply to move around the transport system, is associated with poorer health and quality of life (O'Neill et al., 2019).

Are Automated Vehicles the Answer?

The advent of automated (self-driving) vehicles has been proposed as a way of solving the problem of eventual decline in safe driving ability with age: on the one hand, it is similar to a shift to standard public transport, except that it is more accessible; and on the other, the level of protection will be high. However, population aging is already proceeding at a rapid pace, while widespread use of fully automated vehicles may be many years away.

In the meantime the vehicle sector is experiencing a transition through the different levels of automation from a completely non-automated car (Level 0) to a fully automated car (Level 5). The lower levels of automation involve ADAS such as navigation systems which (as noted above) elderly drivers find distracting. For in-vehicle information systems in general, elderly drivers experience greater levels of cognitive and visual demand, and take longer to complete their interactions.

A significant issue prior to full automation is the need for drivers to take over control of an automated vehicle when unexpected circumstances arise. Although research in this area is limited, there is sufficient information to suggest that elderly drivers will find taking over control of an automated vehicle to be significantly more challenging than younger drivers. This field is evolving rapidly, however, and artificial intelligence approaches to perceiving and interpreting traffic situations may eventually be central to safe automated driving for all ages of driver.

Introduction

Many nations have organized emergency response systems to address natural, technological, and human-caused disasters. In most nations, the current emergency management structure began as a civil defense mechanism, often with the military in the lead, augmented by local volunteers. Many nations, such as China and Japan, still have a primary role in emergency response for the military resources. For example, after earthquakes the military units provide search and rescue and mass care services to local communities (Edwards et al., 2015). Great Britain has organized around the public safety services at the field, and administrative professionals in coordination roles, ultimately reaching up to Cabinet-level positions, using the Gold/Silver/Bronze system. Italy has adopted the Incident Command System nation-wide, developing identical training, and equipment caches in all regions to facilitate a coordinated response and effective mutual aid (Edwards and Steinhausler, 2007).

The United States of America (US) has a multilevel approach that starts with the municipality, and includes the state and the federal government in delivering services and support. The field level may have the fire service as the incident commander in a life-safety disaster, law enforcement as the incident commander in a criminal or terrorist disaster, or even public works in a flood or infrastructure-related disaster. The community's city leaders open an emergency operations center to provide coordinated support to the field forces. The US system is explained in detail, and might be a useful model for other federal nations.

The emergency response system in the United States is based on the National Incident Management System (NIMS), and the National Response Framework (NRF) and its component parts (DHS, 2019). The fourth edition of the NRF was issued in October 2019, describing the overarching systems for responding to emergencies, disasters, and catastrophes throughout the United States. It includes Emergency Support Function (ESF) #1—Transportation, and in 2019 added a new ESF #14 that is focused on cross sector issues, including supply chain transportation.

Transportation is designated as a critical infrastructure within this system. Transportation's role in providing road access, evacuation routes and capabilities, access and egress to the site of an emergency, and support of logistics activities makes transportation central to emergency response. Transportation is also the key to the national and international supply chain on which the economy depends. Transportation in turn depends on electricity for signals, pipelines for fuel delivery, and communications and information technology resources for the management of the service delivery systems.

All Disasters are Local

The current American approach to emergency response derives from lessons learned during the terrorist attacks on the United States on September 11, 2001 (9/11). The immediate emergency response to the plane crashes was the responsibility of the local governments' first responders, as fire fighters and paramedics tried to put out fires, rescue survivors, and deliver immediate medical care, while law enforcement personnel managed traffic, interviewed witnesses and survivors, and collected crime scene evidence, and transportation personnel provided traffic control and engineering services. Homeland Security Presidential Directive 5 (HSPD-5) recognizes that "Initial responsibility for managing domestic incidents generally falls on State and local authorities" (Bush, 2003, Section (6)).

World Trade Center

Two commercial airplanes were flown into World Trade Center Tower One and World Trade Center Tower Two, causing structural damage to the buildings and fires fueled by the jets' fuel, building contents, and diesel fuel stored in the buildings to operate the emergency generators. In less than 2 h, after the air crashes, both towers had collapsed (Edwards and Steinhäusler, 2007). The collapse of the two towers destabilized the plaza on which they were sitting, and caused World Trade Center Building Seven to collapse. Debris from the falling towers did irreparable damage to the rest of the World Trade Center buildings, all of which had to be demolished. The subway and Port Authority Trans Hudson (PATH) train stations under the World Trade Center were severely damaged, and the plaza had to be shored up to prevent further damage to the city's transit systems (Jenkins and Edwards-Winslow, 2002).

The scope of the World Trade Center disaster was so great that managing it effectively was difficult. The two collapsed towers left a smoldering pile of debris that included hundreds of people who had been inside. Volunteers from public safety departments across the nation arrived to help with the search and rescue, and ultimately search and recovery, work. While New York State Department of Environmental Services Police forces patrolled the perimeter to prevent unauthorized access, a lack of a formal check-in systems meant that uniformed personnel were generally permitted access to the pile. Coordination of the multiple personnel from various jurisdictions and professions was impossible (National Commission on Terrorist Attacks, 2004).

In New York City, Mayor Rudy Giuliani became known as "America's mayor" as he appeared on television giving updates on the World Trade Center response and rescue efforts, and delivering calming messages to the public. Local public health agency and fire department personnel responded to the elderly residents who were stranded when the South of Houston area was evacuated, and they were unable to leave their walk-up apartments (Jenkins and Edwards-Winslow, 2002). New York City Transit (NYCT) and Metropolitan Transportation Authority (MTA) engineers designed the shoring systems used to protect the subway systems from further damage, after the World Trade Center Towers collapsed, and the plaza on which they sat was destabilized. Iron workers and welders from NYCT and MTA joined the police and fire personnel working on "the pile"—as the Tower One and Tower Two building collapse area was known—to cut large pieces of steel that had survived the collapse to open the way for rescuers. Transit heavy equipment operators removed large debris, and took down the remains of damaged World Trade Center buildings that remained partially standing (Siano and Joseph, 2002).

Federal Emergency Management Agency (FEMA) personnel helped to organize additional assistance from outside of New York City, but the initial response in the first crucial hours was conducted by personnel from New York City and its immediate neighboring jurisdictions. FEMA leaders often affirmed that "all disasters are local", even in this catastrophic attack because, the first people to arrive at the scene and help the survivors are local public safety and public works personnel. Assistance from outside entities and federal organizations comes later, and most often in the form of specialized teams like search and rescue and medical teams, or as funding for contracting with specialized resources.

Pentagon

The Pentagon was the second site attacked by terrorists on 9/11. The building is the Department of Defense headquarters, and so served as a symbol of America's military might. It was built during World War II, and was undergoing renovation when the attack occurred. The building has five sides—thus its name—and three interior corridors that decrease in length moving toward the courtyard in the center. The five sections are called wedges. The wedge that was struck by the airplane had just completed its repairs and was starting to be repopulated, which accounts for the low occupancy of the wedge that was the site of the direct hit. The plane flew through the wedge, stopping before crossing the interior courtyard, causing a fire and partial collapse of the interior structures (National Commission on Terrorist Attacks, 2004).

The Arlington County, Virginia Fire Department was the fire and emergency medical response agency. They had practiced fire drills with Pentagon staff and had a good history of collaboration across civilian and military organizational lines using the Incident Command System (ICS) (National Commission on Terrorist Attacks, 2004), which is described in detail later.

ICS had been created in southern California in the early 1970s, after multiple fire departments worked together on large wildland urban interface fires in Malibu Canyon, Topanga Canyon, and Escondido. Based loosely on the US military's hierarchical structure, it became the western United States' proven method for multi-agency command and control in firefighting.

The National Fire Academy had begun teaching ICS as a best practice in the 1980s, and Arlington Fire Department was among those that adopted it. On 9/11, Arlington Fire Department Assistant Chief James Schwartz used ICS to manage the response to the Pentagon fire, building collapse and multiple casualty incident, coordinating the response with the Federal Bureau of Investigation (FBI) and military authorities (Titan Systems, 2002).

The ICS provides a hierarchical organization that defines the work of an emergency response—command, operations, planning/intelligence, logistics and finance/administration. It includes a safety officer within the command section and a check-in/check-out procedure in the planning/intelligence section. These structures ensure that all personnel operate safely, using the proper safety equipment, and that they are accounted for at all times. All personnel are assigned to a specific supervisor, and these assignments are recorded on a board to ensure that everyone has oversight during the operation (Edwards, Goodrich & Griffith, 2015). The Pentagon grounds are secured by the military, so controlled access to the crash site was already established and maintained by the Pentagon's military police (National Commission on Terrorist Attacks, 2004).

In the after action report on the Pentagon attack, the Incident Command System was identified as a practice “that others should emulate” (Titan Systems, 2002, p. 11). The response to the Pentagon was judged to be a comprehensively successful emergency operation, in contrast to the less structured response in New York City (National Commission on Terrorist Attacks, 2004). As a result, ICS was recognized as a successful management tool for multijurisdiction, multidisciplinary emergencies.

Emergency Response Structures

Incident Command System

ICS originated in the southern California fire service in the early 1970s. After providing mutual aid to each other in several major wildland urban interface fires, the fire chiefs of southern California, the California Division of Forestry and the U.S. Forest Service created an organization, Firefighting Resources of Southern California Organized for Potential Emergencies (FIRESCOPE) that oversees the development of ICS doctrine and training resources. They publish the *Field Operations Guide* that provides a checklist for every position of the ICS (U.S. Fire Administration, 2016). Within a few years, the ICS method had spread throughout California and to other western states. In the 1980s, it was also adopted as a best practice by the National Fire Academy.

ICS is used to manage emergencies in the field. It is based on a hierarchy that ensures unity of command. It is also flexible, allowing the Incident Commander to staff the four general staff sections as the event requires, retaining all unstaffed responsibilities. It is based on common terminology, so that public safety staff members from different communities or professions can communicate effectively during an emergency. All event-related communications are to be conducted in plain English—no codes—to ensure that all participating professions and departments have a clear understanding of what is being said.

ICS has five main functions: command at the top with four subordinate functions—operations, planning/intelligence, logistics, and finance/administration. The command leader is in overall charge of the event, and is called the Incident Commander (IC). The IC is supported by the command staff consisting of a public information officer, safety officer and liaison officer. The other four sections are collectively called the general staff. The ICS elements jointly operate out of an Incident Command Post (ICP), which may be as simple as the back of the IC’s vehicle at a house fire, or as elaborate as a portable office complex at a large scale wildland fire. The IC makes the decisions on how to attack and resolve the emergency, usually with input from the general staff. The IC determines what actions to take, within what timeframe, and with the resources at hand. The plan may include a list of additional resources that must be obtained for future operational success. These decisions, along with a map of the event, an organization chart of the staffing, and any supporting plans and materials, are collected by the Planning/Intelligence Section Chief, and turned into the Incident Action Plan (IAP). This is posted at the ICP for the use of all ICS sections. In a large event, it may be printed and distributed in writing.

The Operations Section Chief is in tactical charge of the personnel who are working to resolve the event. He takes the IAP of the IC and applies the directions to the resolution of the event. Branches under Operations usually include firefighting, search and rescue, hazardous materials, law enforcement, emergency medical services, and transportation. Operations personnel assesses the damage and analyzes conditions related to safe operations around damaged buildings and structures.

The Planning/Intelligence Section Chief oversees the collection of vital information about the event, makes maps of the event, creates situation status reports, documents all activities at the event, and develops the demobilization plan for the end of the event. Resource accountability is managed through the check-in/check-out function for personnel, and a resource tracking system for goods and services that have been requested, received and returned. Staging areas are designated for stockpiling requested goods, and holding personnel and equipment that has been received, but not yet deployed.

The Logistics Section Chief is responsible for all support services for the event. The communications unit is responsible to provide standard fire radio systems, Internet connections and cell phone services. Some jurisdictions also have interoperable radio systems that allow fire, law enforcement and emergency medical services personnel to speak on a common frequency. The Personnel Unit arranges for additional staffing, staffing for shift change, and tracks overtime costs. The food unit organizes meals for the responders. Other units may include procurement, to acquire additional resources, facilities to acquire space for activities, and transportation to acquire heavy equipment or nonfire support vehicles.

The Finance/Administration Section Chief is responsible for tracking all costs associated with the event, and to document costs for potential reimbursement from responsible parties or higher levels of government. For example, during terrorist events or catastrophic natural disasters, the federal government may reimburse up to 75% of the documented emergency response costs (FEMA, 2016). Units include compensation and claims, cost recovery, and timekeeping.

At the end of the operation, an after action review is held that involves all the section chiefs and other key participants in the field-level response. An open discussion includes what actions went well, what strategies need to be changed, and what activities failed or were not productive and should be eliminated from future responses. This AAR analysis is written as a report that includes a summation of the event, its outcomes, and an improvement matrix aimed at incorporating the lessons learned from the management of the event into organizational doctrine and plans to guide future emergency response (U.S. Fire Administration, 2017).

Emergency Operations Centers

Most jurisdictions also have an Emergency Operations Center (EOC), which may be found at the city, county, special district and state levels. The National Operations Center (NOC) is the EOC for the Department of Homeland Security. While ICS focuses on the

tactical management of an event at the field level, the EOC manages the event from a strategic perspective, considering the needs of the emergency and the unaffected portions of the community (FEMA, 2017). The EOC goes beyond the public safety services and accesses resources across all jurisdiction departments. For example, at an apartment house fire, the IC would be focused on moving victims out of harm's way, while the care and shelter unit of the EOC would collaborate with the transit agency to get busses to move the victims to shelter, and the Non-Governmental Organization (NGO) community to open a mass care center with food, sleeping accommodations, and medical surveillance. This might include social services case work and connecting survivors to community-based support services and government assistance programs.

In many states the EOC is organized using ICS. The main difference is that the top position is the Management Section headed by the EOC Director, whose role is strategic (management) rather than tactical (command) as in the field. The general staff positions are the same as in ICS, and generally fill the same roles, albeit with an eye to larger community concerns as well as emergency response needs (Edwards and Goodrich, 2012). For example, the community's fire chief might be the Operation Section Chief in the EOC, and have to consider deploying resources for the ongoing emergency, while recognizing the need to respond to developing individual emergencies, like calls for medical services from unaffected community members.

The EOC can also provide more complex support elements, such as GIS mapping, situational status reporting to higher levels of government, and updating elected officials regarding the emergency event. The Management Section Chief can also advise the governing body on whether to declare a local disaster, and begin the process of requesting assistance from higher levels of government.

Some communities prefer not to use ICS in the EOC. NIMS 2017 offers two other options. Jurisdictions might use the Incident Support model, in which the EOC is focused on information, planning and resource support. The jurisdiction's leadership retains the EOC Director role, but this model separates situational awareness functions from planning, creating two sections, merges Operations and Logistics to form a resources support section, and leaves the finance functions in a center support section. The other option is called the departmental structure. The EOC is organized around the jurisdiction's normal departments, with the day-to-day leader as the EOC Director, supported by the department heads whose resources have to be part of the emergency response (FEMA, 2017).

National Incident Management System

Following the 9/11 attacks, new structures were created to encourage the development of nationwide coordinated systems for responding to future terrorist attacks or natural hazards events. President George W. Bush issued HSPD-5: Management of Domestic Incidents (2003). HSPD-5 Section 15 directs the Secretary of the Department of Homeland Security (DHS) to create the National Incident Management System (NIMS), based on ICS and its components.

Complying with HSPD-5, DHS created NIMS in 2004, and updated it in 2008 and 2017. NIMS incorporates the use of ICS in the tactical field response, and the creation of emergency operations centers for strategic incident management at all levels of government. "NIMS applies to all incidents, from traffic accidents to major emergencies" (FEMA, 2019, n.p.). NIMS applies to government agencies at all levels, to the non-governmental sector (NGOs), and to the private sector. Thus, all elements of transportation are required to use NIMS in emergency response. This comprehensive approach is reiterated in the Federal Highway Administration's (FHWA) Manual of Uniform Traffic Control Devices (MUTCD) which states, "The National Incident Management System (NIMS) requires the use of the Incident Command System (ICS) at traffic incident management scenes" (FHWA, 2009, p. 726), where multiple public safety entities and private sector organizations may be coordinating to resolve the event.

Like ICS, NIMS is based on flexibility, standardization and unity of effort. It addresses all phases of emergency management: prevention, protection, response, recovery and mitigation. It focuses on three areas: resource management, command and coordination, and communication and information management. While ICS assigns the public information officer to the IC in the field, or the EOC Director, NIMS creates a Joint Information Center, where PIOs from the responding agencies work together to create a unified message across jurisdictions and professions based on a common operating picture. Communication across jurisdictional and professional boundaries is a key tenant of NIMS, along with the creation of the common operating picture based on incident reports and IAPs. (FEMA, 2017)

National Response Framework

The National Response Framework (NRF) is the guide that operationalizes the NIMS emergency response element. The fourth edition was issued on October 28, 2019 to add more focus on community lifelines in emergency preparedness, response and immediate recovery activities (first 72 h). As a result of lessons learned during the 2017 disasters—floods, wildland fires and hurricanes—the framework changed the orientation of the response to developing outcomes—"What exactly are we trying to achieve?" (FEMA, 2019). Recognizing that 85% of the lifeline services are privately owned—such as electrical utilities, fuel pipelines, and supply chain transportation vehicles—the fourth edition stresses the need for "a larger and more focused role" for the private sector, and includes the development of a National Business Emergency Operations Center. (DHS, 2019c, p. ii). During Presidentially declared major disasters, FEMA has daily calls to coordinate logistics requests, recognizing that "government alone cannot meet community needs", and "the private sector can solve problems better because, they do it every day" (FEMA, 2019). The lifeline construct defines seven sectors: safety and security; communications; food, water and shelter; transportation; health & medical; hazardous materials; and energy, power and fuel.

The National Response Framework includes fifteen ESFs (DHS, 2019a). The federal government organizes its response resources around these, including ESF #1—Transportation (DHS, 2016), and ESF #14—Cross Sector Business and Infrastructure (DHS, 2019b). Each ESF has a lead agency, and many other federal agencies that provide support and resources.

Emergency Support Function (ESF)-1 Transportation

The US Department of Transportation is the coordinator and lead agency for ESF #1, while 10 other federal agencies are in support. ESF #1 responds to requests from local, state, territorial and tribal governments, and in support of NGOs and the private sector, for disaster assistance. They can mobilize federal resources, or they can contract with the private sector to provide the needed services. For example, they may coordinate with the Department of Defense to provide “high water vehicles”—trucks with very large tires—to take supplies to flooded communities, or contract with a tour business for limousine busses to evacuate survivors away from a devastated community. The state receiving the assistance pays a 25% cost share for the resources during a Presidentially declared major disaster. Some states in turn share this cost with the municipality or county, where the disaster occurred.

Emergency Support Function (ESF)-14 Cross Sector Business and Infrastructure

The Department of Homeland Security’s Cyber and Infrastructure Security Agency (CISA) is the coordinator for ESF #14, with CISA and FEMA as the primary agencies, and 15 federal departments and agencies are in support. While transportation needs of communities, NGOs, and the private sector may still be met primarily through ESF #1, ESF #14 was created to ensure cross-sector coordination, such as the need for supply chain and lifeline stabilization. For example, transit systems rely on electricity for powering the trains, for providing street-level traffic signals for busses to travel safely, and for fare-related transactions like purchasing tickets or using a credit card for passenger access to the system. Supply chains rely on global positioning systems, fuel delivery, and open roadways. All of these systems rely on communications, including telephones, radios, and the Internet. The goal of ESF #14 is to ensure that these interconnected systems recover in a coordinated and expeditious manner to restore services to the impacted communities. While public transit and transportation organizations would still coordinate primarily through ESF #1, the ability to have cross sector linkages with privately owned fuel supplies and power operators could enhance response and recovery activities (FEMA, 2019).

Critical Infrastructure

Presidential Policy Directive-21 names 16 sectors as critical infrastructure. They represent assets, systems and networks whose loss would debilitate national safety and security. Transportation Systems is one of the sectors (DHS, n.d.). The Department of Homeland Security (DHS) and the Department of Transportation (DOT) partner ensure that people and goods move safely and securely to domestic and overseas destinations. Cyber security is an important part of this sector’s functioning, with its dependence on supervisory control and data acquisition (SCADA) systems for operations, computer-based traffic signals, global positioning systems (GPS) for navigation, radio frequencies for positive train control, the Internet, and cell service. The focus of transportation sector security is on understanding and managing risk to avoid emergencies (DHS, DOT, 2015), but natural hazards, technological accidents, and terrorist attacks can all impact these systems, regardless of the validity of the risk analysis and mitigation efforts. Therefore, effective emergency response to the transportation sector’s critical infrastructure is the fallback when preparedness fails.

Sector-Specific Agencies

Sector-Specific Agencies (SSA), in this case DHS and DOT, maintain plans for emergency response that conform to the requirements of the National Response Framework, in compliance with HSPD-5 and Presidential Policy Directive (PPD)-8 that calls on the whole community to collaborate for emergency preparedness and response (DHS, 2011). The transportation sector supports evacuation, rescue, medical care and incident management (DHS, DOT, 2015). Its activities are aligned with the National Infrastructure Protection Plan (DHS, 2013), and focus on preparing for terrorist attacks through “identify, deter, detect, and deny access” strategies, and on mitigating the impacts of natural hazards through redundancy and cross sector collaboration.

Mutual Aid

Not all local government jurisdictions are capable of managing all emergencies on their own. Few have the local resources to manage catastrophic events, especially, when the first responders are victims themselves. For example, the response to the 9/11 World Trade Center attack included personnel from jurisdictions all over the United States, and even volunteers from other countries. Today mutual aid is delivered through organized systems, including local and state mechanisms for coordinating assistance requested by the jurisdiction at risk. For example, in California, there is a statewide mutual aid system for police that is coordinated by the sheriffs of the counties, and a fire mutual aid program that is coordinated by the county fire chiefs. Building officials’ mutual aid is managed by volunteer coordinators who are members of the Structural Engineers Association of California (SEAOC), and emergency managers’ mutual aid is managed by the Governor’s Office of Emergency Services (California OES, 2012). In most states, the requests for mutual aid are generally coordinated through the state’s office of emergency management and its regional components, and may be delivered for free or with specified reimbursement costs.

The Emergency Management Assistance Compact (EMAC) is a national organization that coordinates state-to-state assistance. EMAC receives requests for assistance and circulates the requests to the other states. States respond to mutual aid requests with offers of resources and their costs, including overtime, equipment use fees, travel, and per diem expenses (EMAC, 2020).

The Role of Transportation in Emergency Response Systems

As demonstrated by its position as ESF #1, transportation capability underpins all other emergency response. The physical elements of the transportation system constitute critical infrastructure, which may be owned by local governments—city streets and county roads—the state or the federal government. Until the roads have been cleared of debris and the bridges have been inspected and found passable, the rest of the emergency response cannot proceed into the disaster area.

The first responders may need to be transported to the site of the emergency. Residents of the disaster area may need to be evacuated to a safer location, or even out of the state, as was the case in Hurricane Katrina. This will require not only safe roadways, but also busses from both public transit agencies and private sources. All this movement of first responders and residents requires a reliable supply of fuel—for the debris clearance vehicles, for the road and bridge inspectors' vehicles, for the transit vehicles, and for private vehicles as residents evacuate themselves. Immediate recovery requires robust transportation capability. Food, water, diapers, baby formula, and building materials need to be brought into the community to care for the survivors and begin emergency repairs and short-term recovery.

State-level transportation agencies are responsible for the state highway system and elements of the national highway system in their jurisdiction. They also coordinate intercity busses and general aviation, which may be additional assets in disaster response. They inspect the infrastructure for safety, and issue overweight permits for heavy equipment that has to travel into the disaster area, especially if the highway system roadways are impassable. The state transportation agency is often the point of contact for ESF-1 in the state's emergency operations center, tying together the needs of the disaster survivors with national assets, public and private.

Background

Emergency response services are an integrated part of our modern society with the overarching role of ensuring public safety and security. Emergency vehicles (EVs), such as ambulances, police cars, and fire trucks, are fundamental components of most emergency response systems. EV ensures timely response to the scene of emergency and delivery of vital services during an emergency. Road traffic crashes involving EVs responding to an emergency situation may lead to significant delay in the time of emergency response. It will also reduce the capacity and efficiency of the emergency response system. Therefore, road traffic crashes involving EVs are considered to have greater societal and economic impacts than a regular crash as these unfortunate events contribute to additional difficulties for the people already in distress. The social costs of EVs involved in road traffic crashes are thus expected to be higher than other road traffic crashes (NHTSA, 2011). Moreover, if an ambulance carrying a patient gets involved in a road crash, it not only poses a threat to the patient along with EV occupants and other road users (if involved), the situation also gives rise to the violation of core medical principle of “first do no harm” (American Medical Association, 1903).

The crash-related vehicular claims (Compulsory Third-Party Claim) also impose greater liabilities for emergency agencies. Because of their liabilities, EV drivers are generally also under greater scrutiny than other occupation-related driving. Moreover, EV crashes are considered as high-profile crashes and tend to attract significant media attentions. Also, although crashes involving EVs represent a small proportion of road traffic crashes, they are reported to be more severe than other crashes mainly because of the operational differences between these two groups of road users. Therefore, road traffic crashes involving EVs are major concerns not only for road users involved but also for the relevant authorities and the wider community.

EV Crash Statistics

Motor vehicle crashes are the second leading cause of firefighter deaths in the United States (Donoughe et al., 2012). From 2000 to 2009, more than 31,600 crashes involved fire trucks in the United States (Donoughe et al., 2012); while between 2004 and 2013, 179 firefighters died as a result of road crashes (U.S. Fire Administration, 2014a). They are likely to be killed after being struck by vehicles while either directing traffic or performing roadside emergency rescues. EV crashes involving other road users also pose greater threat to the occupants of other vehicles, pedestrians, and bicyclists. From 1996 to 2012, 137 civilian fatalities and 228 civilian injuries were reported from fire truck-involved crashes (U.S. Fire Administration, 2014b). Among 107 fatalities involving fire trucks between 1997 and 2006, 94 fatalities were other road users involved in these crashes. In Europe, six Swedish firefighters died as a result of traffic crashes in the 5-year period 2012–16. They died mostly from single-vehicle

crashes but at least one firefighter was killed when hit by a motor vehicle while outside their vehicles. Although there were more fatalities in the United States, Sweden's fatality rate per population is 1.2 fatalities per year, which is higher than that in the United States. With the Swedish rate, we would expect around 38 firefighter fatalities per year in the United States instead of just 179 in ten years.

In the United States, ambulances are reported to be involved in more than 6500 crashes per year, 35% of which are associated with at least one injury and/or fatality (SFTLA, 2019). Road crashes are identified to be the first leading cause of occupation-related fatalities among emergency medical service (EMS) personnel. In fact, occupational road crash-related fatalities are 4 times higher and crash risks are 20 times higher among EMS personnel relative to other occupations (Maguire and Smith, 2013). In Great Britain, between 1999 and 2004, a total of 38 fatal crashes and 204 serious injury crashes involving ambulances were documented (Lutman et al., 2008). Crashes involving ambulances were documented to result in 64 civilian fatalities and 217 civilian injuries between 1996 and 2012 in the United States (Hsiao et al., 2018). In Sweden, 2003–13 saw 173 police-reported crashes involving ambulances, injuring 218 people in the ambulances, 26 of them seriously injured. A majority of the seriously injured were emergency medical technicians in the back of the ambulance, unable to wear seat belts while performing their duties. Two people died because of these crashes. One was a driver and one was a passenger. A recent in-depth study of injury crashes involving ambulances in a county in Sweden showed that the ambulance driver was the prime contributor (caused) 80% of the crashes. As a result of the study, a 2018/19 bill in the Swedish parliament was passed which gave the government a charge to develop a nationwide mandatory training program of ambulance drivers. Before the legislation, drivers of EVs do not need a specific license but anyone with an automobile license can drive an ambulance or police car and anyone with a truck license can drive a fire truck. However, to drive a taxi in Sweden, a driver needs extensive training beyond a normal driver's license.

In terms of police cars, in the United States, this EV is reported to be involved in 300 fatalities each year (SFTLA, 2019). Between 1998 and 2008, 50% of fatalities among law enforcement officers were reported to be from road crashes. In Australia, police car crash risk is identified to be 11.8 crashes per million kilometers traveled. It is also reported that police pursuits result in relatively higher crash risk representing one crash per 120 kilometers traveled (Symmons et al., 2005). In the United States, from 1979 through 2013, crashes involving police cars resulted in more than 2400 civilian fatalities (Hsiao et al., 2018). It has also been reported that 18% of police fatalities occur when officers are working near speeding motor vehicles, directing traffic or issuing traffic summonses either on the road or on the side of the road (Clarke and Zak, 1999). In Sweden, in the 10-year period 2003–12, at least 9 people were killed and 1457 injured in crashes involving police cars. These numbers do not include injuries and fatalities in crashes caused by police pursuits if the police car was not involved (damaged) in the crash. Comparing fatality rates on a population basis, Sweden's 0.9 fatalities per year would be comparable to 29 fatalities per year in the United States. Thus, the United States has roughly 10 times higher fatalities than Sweden, probably a reflection of police pursuits being very rare in Sweden. Also, it is rare to see a police vehicle in Sweden travel above the posted speed limit whereas that is common in the United States.

Overall, between 2001 and 2010, more than 0.3 million EVs were involved in road crashes in the United States. Among these crashes, 49.3% of the fatalities involving EVs occurred when EVs were operating in emergency mode with lights and sirens (NHTSA, 2001–2010). The national crash fatality rates, in the United States, for EV personnel are 2.5–4.8 times higher than national average for all occupations (Savolainen et al., 2009). EV crashes often also incurred in many lawsuits costing millions of dollars due to the loss of lives, the associated injuries, and property damages. It is estimated that the global cost of EV accidents is \$250 billion annually. In the United States, the cost of EVs is computed to be \$35 billion annually (SFTLA, 2019).

Objective and Scope

Despite the growing concerns and the impacts of EV crashes, there have been few studies in understanding the issues related to this crash type. These studies tend to focus on the determinants of crashes and severities, emergency operations, driver behavior, and distractions. Nevertheless, these studies have important implications in identifying countermeasures and in identifying critical areas in driver training to improve EV safety. Therefore, this paper will review the research on EV crashes, and discuss the critical factors contributing to crash risk, injury risk, and severity outcomes of crashes involving EVs. It will also discuss the different sources of EV crash data and the analytical approaches employed in existing safety literature.

The rest of this paper is organized as follows. First, this paper will discuss details of EV crash analysis while focusing on EV crash data, analytical contexts, and methodological overview. Second, a summary of the contributing factors related to EV crash analysis will be presented. The third section will present a research framework for safety analysis and examination of EV-involved crashes. Finally, insights and concluding remarks will be presented. It should be noted that the impact of different policy inventions, in terms of education, engineering, and enforcement strategies, and impacts of these interventions on EV safety are beyond the scope of this paper.

Analyzing Emergency Vehicle Crashes

Emergency Vehicle Crash Data

In evaluating critical factors contributing to EV crashes (crash risk and severity outcome), police-reported crash databases have thus far been the most prevalent data used in traffic safety research. These crash databases generally compile detailed information on crash characteristics, driver characteristics, environmental attributes, roadway attributes, and vehicle characteristics. However, these crash

databases do not generally include information on driver actions or behaviors and information on emergency operations. Therefore, by using these crash data it is often difficult to understand the impact of driver actions and emergency driving conditions on crash risk and severity outcomes.

Occasionally, researchers have used crash records along with dispatch information from different emergency department data repositories (Bui et al., 2018). These databases have greater scopes in terms of quantifying the relative risk of EV crashes with regard to their actual exposure. EVs equipped with telematics and black box are useful sources of information for monitoring driver actions and vehicle trajectories, including driving speed, acceleration, and braking actions. These secondary data sources (if available) can be used to develop more robust decision support tools to improve EV safety by incorporating driver actions and driving conditions critical to EV safety.

It is worth noting that many safety researchers continue to mainly use police-reported crash databases for EV road safety studies since the cost associated with obtaining these secondary data is much lower than collecting primary data themselves. Nevertheless, road safety analyses can still be enhanced by integrating information from emergency departments and police-reported crash databases. But such data pooling approaches, in identifying critical factors contributing to EV crashes, are far and few between.

There are also several other proactive data sources that may have greater scopes in evaluating critical EV-related crash factors, including surveys, and driving simulation. These data can be used to understand drivers' perception, EV operational influences, and behavior of civilian road users on roadways in the presence of EVs. These alternate data collections and analysis approaches have yet to be explored in EV crash safety studies.

Analytical Contexts

Existing studies have predominantly focused on identifying critical factors related to EV crash risk. Due to the lack of real-world EV exposures data, the evaluation of EV crash risk were mainly focused on the severity outcomes or the comparison of EV versus other vehicle crashes. Also, a few studies have compared crash factors under emergency versus nonemergency operation of the EVs involved in crashes (Pirrallo and Swor, 1994). Given the differences in response categories of different EVs, it can be presumed that the crash mechanisms of these vehicles will be fundamentally different. Therefore, some studies have identified differences among critical factors contributing to crashes involving ambulance, police car, and fire truck (Becker et al., 2003; Symmons et al., 2005). Moreover, given the differences in roadway environment between urban and rural crash settings, a number of studies have identified differences in factors contributing to EV crashes between two traffic environment conditions (Ray and Kupas, 2007). Evaluation of EV driver actions was also focus of few studies (Yasmin et al., 2012).

In terms of disaggregate-level crash severity analysis, few studies have analyzed the contributions of variables in EV crash severity outcomes, with major focus on EV occupant severity. The injury severity profiles of occupant in other vehicles involved in crashes with EVs are likely to be fundamentally different due to the differences in driving characteristics and vehicle compositions. However, none of the studies have identified the differences in injury severity profiles between EV and other vehicle crash victims. It is also surprising that none of the earlier studies have developed macro or planning-level models to identify critical factors contributing to aggregate-level EV crash counts over time. Outcomes of such macro-level EV crash count models might be useful to provide us with insights on EV dispatch origin and destination relative to clusters of EV crash locations (if available). Moreover, these studies will allow us to identify the plausible relations between EV crash risks and built environment.

Methodological Overview

Statistical methodologies are used by researchers in many different fields, including transportation safety, to glean information from existing data sources. Depending on the level of analysis, the studies examining EV crashes can broadly be classified into two categories: (1) aggregate-level descriptive analyses (based on univariate or bivariate associations at the aggregate level)—these studies are presented in the first row panel of Table 1, and (2) disaggregate-level multivariate analyses—these studies are presented in the second row panel of Table 1.

The majority of the previous studies fall in the first category. Using aggregated data, these studies either conduct simple qualitative or descriptive analysis or use nonparametric (distribution free) tools, such as χ^2 statistic or Fisher's exact test statistic to analyze group differences. There are two caveats associated with these types of analyses. First, aggregation of data might lead to loss of information. Second, the methods are explorative and hence, drawing causal inference is not possible. As a result, their policy implications and practical applications are quite limited.

Disaggregate-level analysis can extract richer behavioral insights that lead to more meaningful, accurate, and policy-relevant findings. Despite the clear advantages, application of multivariate methods is fairly rare in EV crash analysis. The studies in this category generally use binary logit and probit models to identify: (1) the factors associated with emergency and nonemergency pursuits or (2) the risk factors associated with fatal and injury outcomes. To differentiate between factors affecting crashes involving different EVs (police, fire truck, ambulance), multinomial logistic regression is also used. On the contrary, ordered logit model and its variants (e.g., generalized ordered logit model) have been used in occupant injury severity analyses as these are recorded in ordinal and discrete categories such as property damage only, minor injury, major injury, and fatal injury.

There has been continual and substantial progress in road safety research methodology in recent years—fueled primarily by the enormous increase in computing power and the need to overcome the limitations of the publicly available crash data. Researchers have developed methodologies that can accommodate (1) systematic and unobserved heterogeneity, (2) endogeneity

bias, and (3) within crash as well as temporal and spatial correlations. However, these methods are yet to be applied to EV crash analysis although it is very likely that unobserved heterogeneity, endogeneity bias, and temporal variability might be present in the context of EV crashes. For example, driving EVs while responding to an emergency call entails driving in stressful conditions. Different drivers (even though they are highly trained) will adapt and react to these situations differently, which may result in unobserved heterogeneity in the event of a crash and its outcome. This heterogeneity can result in biased or inefficient parameter estimates. To address this concern, more generalized modeling framework such as random parameter or latent segmentation-based models need to be applied. Moreover, no study has systematically attempted to identify exogenous variables that offer time-varying effects and quantify the changes in their impact. Over the years, continual advance has been made in in-vehicle safety features, EV regulations, and driver training and monitoring initiatives. Therefore, there is much scope for methodological improvement in EV crash research.

Crash Contributing Factors

Previous research on EV crashes has predominantly focused on ambulance crashes, with very few studies focusing on police vehicle and fire truck crashes. A summary of the earlier studies is presented in Table 1. In the following subsections, factors associated with either the probability of occurrence or the outcome of EV crashes will be discussed based on the studies presented in Table 1. For ease of understanding, the factors are categorized into five groups: (1) crash characteristics, (2) roadway characteristics, (3) environment characteristics, (4) driver characteristics, and (5) vehicle characteristics.

Crash Characteristics

Location is an important factor in both the probability of a crash occurrence and its injury outcome. For instance, the incidence of ambulance crashes is higher in the urban setting. Urban roads typically carry heavier traffic and thus the probability of traffic conflicts and crashes is higher. However, due to high-posted speed limits and dark roadway conditions, rural settings are more likely to result in injuries, and the severity of these injuries is likely to be greater than in urban settings. Interestingly, opposing results are also found in the literature. The contrasting findings might be the result of different study environment, study methodology, sample size, definition of urban and rural settings, and a combination of these factors.

Ambulance crashes involving more people have a higher probability of more injuries because of non-wearing of seat belts by the accompanying members and the emergency personnel in the back of the ambulance since wearing of seat belts inhibits patient care. The presence of unattached object is another potential reason for higher injury risk of rear compartment occupants. Research has also shown that compared to the law enforcement officers and firefighters, emergency medical personnel are at a greater risk of being fatally injured.

In general, ambulances are more likely to be involved in angular crashes while loss-of-control and rollover crashes are the major collision types in which fire trucks are involved. When vehicles are deployed for emergency use, they are more likely to be involved in angular and multi-vehicle crashes. However, ambulances are also significantly more likely to have an impact at the front (resulting from head-on collisions or striking a fixed object) in the rural area crashes, whereas urban ambulances are more likely to be involved in back-end or rear-end collisions.

Roadway Characteristics

Ambulances are more likely to be involved in crashes at four-way intersections, roads with streetlights, and traffic signals in urban areas. This may be due to the other drivers who are supposed to stop and give way to the ambulance may not be stopping when the signal is green. In fact, “failed to notice emergency vehicles,” “failed to yield to emergency traffic” at an intersection, and “failing to

pull over to let a police car pass” in an emergency situation were cited to be the major faults among the civilian drivers. Crashes at intersections or driveways are also more likely to be overrepresented during emergency response.

Environmental Characteristics

Environmental factors are relatively more common in causing rural ambulance crashes. For example, snowy roadway conditions and poorly lit nighttime roads are more prevalent in rural settings whereas the urban crashes are more likely to occur in rain and on wet roads. Also, ambulance crashes are more likely to be injurious on wet pavement, under darkness, during adverse weather, and at intersection. Ambulance crashes occur with increased frequency in the evenings and during weekends. Crashes during emergency use are more likely to occur during the afternoon peak period.

Driver Characteristics

EV drivers are more likely to be passive victims of other road users’ mistakes and violations than being perpetrators of such mistakes and violations. In fact, intoxication of civilian drivers is a major contributor of injury risk in an EV crash. However, distracted driving and poor driving history (record of involvement in multiple collisions on duty) in part of the EV driver is also an important contributory factor. For example, violation of traffic signals by police officers while responding to an emergency or driving in pursuit of another vehicle significantly increases the probability of crashes causing injuries. Also, the age of police officers plays a significant role in the probability of injuries, with young officers (<30 years) being more likely to be involved in crashes causing injury than older drivers while on an emergency run. A 2009 Swedish study of 1763 police officers injured in road crashes shows that out of the 76 who were seriously injured or killed, 27 were below age 30, 28 were 30–39, 17 were 40–49, 3 were 50–59, and 1 was above age 60. Also, 59 were men and 17 were women. Without knowing exposure by age or gender, this does not express risk, but it is clear that younger men are involved in a majority of the serious crashes. However, as opposed to the data from the United States, in Sweden, the police officer was deemed to be at fault for a majority (57%) of the crashes when two vehicles collided.

Vehicle Characteristics

The color of the car and usage of lights and sirens are important vehicle-related factors associated with EV crash occurrences. For instance, the probability of a visibility-related multiple-vehicle crash or a visibility-related single-vehicle crash for a red fire pumper is 3 times greater than for a lime-yellow fire pumper. The superior visibility of lime-yellow color yields an earlier awareness of the fire pumper’s presence by the civilian driver, thereby resulting in a lower crash rate and lower likelihood of injury or tow-away damage.

The use of lights and sirens during an emergency response has a significant increased risk of being involved in a crash for police vehicles but this is likely to be due to the more risky way in which the vehicle is driven in an emergency. However, driving in emergency mode does not increase the crash risk among ambulance and fire truck drivers (Missikpode et al., 2018).

Research Framework

Traffic crash analysis involving EVs should advance along with overall road safety research. However, there are significant scopes for improvement in EV-related crash analysis in terms of employing advanced methodological approaches, exploring more policy-relevant analyses, and adopting other available crash data sources. This paper therefore presents a simple research framework for safety analysis of EV-involved crashes. The research framework is presented in Fig. 1.

In the first stage of the research framework, relevant theoretical models should be identified to develop a conceptual framework for analyzing for severity and/or likelihood of EV-involved crashes. The choice and foci of the theoretical models should be guided by the aims and objectives of the research. Crash risk theory is employed to identify attributes that result in traffic crashes and propose means to reduce the likelihood of traffic crashes. It is focused on identifying the effective countermeasure to improve the roadway design and operational attributes, vehicle designs, and road user behaviors. While reducing traffic crash occurrence is essential, it is also important to provide solutions to reduce the consequences in the unfortunate event of a traffic crash. Thus, the crash severity theory is employed to examine crash events and identifies factors that impact the crash outcome and suggests countermeasures to reduce crash-related consequences (injuries and fatalities). These associated risk factors are critical to assist decision-makers, transportation officials, insurance companies, and vehicle manufacturers to make informed decisions to improve road safety. The importance of using well-established theoretical models needs to be emphasized.

Next, a set of primary and secondary EV crash data sources should be identified which will provide the appropriate data needed to answer the research questions. In the third stage of research framework, analytical contexts focusing on severity and risk analysis should be identified. The focus is on identifying critical factors contributing to EV crash risk and severity outcomes for which data are available. It should also select the most appropriate research method to analyze the data and answers the research questions. More importantly, it should result in theory and evidence-based recommendations to improve safety. Finally, in stage four of the framework, the design, implementation and evaluation of road safety countermeasures should be conducted.

Figure 1 Research and evaluation framework for safety analysis of emergency vehicles-involved road crashes.

The presented research vision is an abstraction or simplification of analytical approaches that can be employed in identifying the critical factors and the associated countermeasures related to EV crash risk and severity outcomes. Such research vision will help up to better understand the research scope and stimulate further thoughts in facilitating future research in EV crash analysis.

Some Insights and Concluding Remarks

This paper discussed the critical factors, based on existing safety literature, contributing to crash risk, injury risk, and severity outcomes of crashes involving EVs. It also discussed the different sources of EV crash data and the analytical approaches employed in existing safety literature. Moreover, this paper presented a research framework for safety analysis of EV-involved crashes.

We found that in identifying the critical factors contributing to EV crashes (crash risk and severity outcome), police-reported crash databases have so far been the most widely used. The majority of previous studies employed univariate analysis, while only few studies adopted multivariate analytical frameworks for examining critical factors contributing to EV crashes. Most of the previous research on EV crashes has focused on ambulance crashes, with very few studies focusing on police vehicle and fire truck crashes.

In general, the factors that were attributed to higher EV crash risks include urban setting, four-way intersection, traffic signal, evening time, and weekends. The critical factors that were reported to be associated with higher injury or fatality risk outcome of EV-involved crashes include high speed limit, rural setting, dark light, and wet pavement condition.

We also found that there is significant scope for expansion in EV-related crash analysis in terms of employing advanced methodological approaches, exploring more policy-relevant analytical contexts, and adopting other available crash data sources. There has been continual and substantial progress in transportation safety research in recent years—fueled by the enormous increase in computing power and the need to overcome the limitations of conventional crash data. Research on EV crashes can utilize these recent advancements in road safety research.

While earlier research has identified the impact of several attributes contributing to EV crashes, there has been limited research in developing a comprehensive analytical framework to develop an understanding on the extent of the EV crash-related safety concerns. We proposed such a research framework in this paper.

Introduction

Julian Harvey is believed to have been the first to introduce the three E's to road safety: Education, Engineering, and Enforcement. We are talking about the year 1923. Harvey indicated that there are three different fields in which work can be done to improve road safety. To this day, the three E's are referred to. Using the familiarity of the three E's, authors have extended the three E's with more E's: for example, to five E's with the additions Encouragement and Evaluation, or even to seven E's with the additions "Economics, Emergency response, Enablement, and the overarching 'E' of Ergonomics" (Plant et al., 2018). In all these approaches, interventions are covered by one of the E's: vehicle safety, for example, is covered by Engineering, traditional police surveillance by "Enforcement" and a government campaign that aims to discourage the use of mobile devices while driving is covered by Education. Sometimes two E's (Enforcement and Education) are used simultaneously when designing interventions: for example, to supplement traffic enforcement with good communication to make an intervention more effective in terms of behavioral change.

It was not until many years later that attempts were made to place the three E's in a more conceptual framework. In the early 1970s, for example, Haddon (1972) introduced his matrix, in which he used two axes. The one axis reflects the three phases in the crash process (precrash, crash, and postcrash) and the other axis reflects the three components of road traffic: road user, road, and vehicle; hence this matrix consists of nine cells. The Haddon matrix was used to classify crash factors and to indicate crash prevention measures. The use of the Haddon matrix made it clear that other cells are important and deserve our attention in addition to the "pre-crash—road user" cell, the cell that traditionally received a lot of attention in policy and research.

In later years, more attempts were made to facilitate the analysis of crash factors and the ordering of preventive measures. Rumar (1999) described the road safety problem as a product of three dimensions: exposure to risk, crash risk, and injury risk. Adding the "exposure to risk" dimension as a way to promote safety was certainly new. A later attempt distinguished five pillars (UNRSR, unknown). These five pillars combine the components man, road and vehicle with a phase of the crash process (postcrash) and with road safety management. From a conceptual viewpoint, this is not an ideal structure, but apparently it is appealing as it is now being used in many countries (WHO, 2018).

The different phases of the crash process, the three components of road traffic, and the three E's have a (very) long tradition in road safety and they have been part of the different paradigms that were used over the years (e.g., Wegman, 2013).

The concept of "encouragement" can be applied to improve road safety, but has in fact been absent from road safety strategies. Whereas enforcement (punishment, discouragement) has played a role for almost a hundred years and is included in nearly all road safety strategies and plans, encouragement has remained virtually invisible. This is remarkable because research shows that both rewarding and punishing can effectively lead to behavioral changes and that in the dichotomy between punishing and rewarding, traditionally rewarding seems to be preferred for achieving results. What parent in the Western world is not confronted with the "fact" that it is better to change a child's behavior by rewarding good behavior and punishing a child as little as possible?

In the 1930s, the American psychologist Fred Skinner launched his theory of behaviorism which made an important contribution to the idea of rewarding desired behavior (the behavior will then be shown more often), to ignore unwanted behavior (is less frequently exhibited and extinguished) and to punish only if unwanted behavior is dangerous and should be stopped immediately. The disadvantage of punishment would be that it does not indicate what desired behavior looks like. As early as in the 1970s, the Canadian psychologist Albert Bandura introduced the phenomenon of "observational learning" or "social learning": a good example will be keenly followed. The fact that these two gurus of behavioral influence and learning both prefer reward rather than

punishment raises the question why rewarding has not been used much more to influence traffic behavior to ensure safer road traffic?

A number of ways to influence behavior will be discussed in this chapter. But it is good to give a perspective on the causes of road crashes, because such a picture is required to answer the question of how effective and efficient it is to use rewarding and penalizing to reduce traffic risks and, consequently, the number of crash casualties. After comparing different types of behavioral influencing, some examples will be given of how rewarding can be used to improve road user behavior. Specifically, this concerns safety management in companies and insurance rewards. The chapter will be concluded with a list of most important lessons learned regarding the application of rewarding.

Causes of Crashes

Crash causes are frequently discussed in road safety literature and nearly always the conclusion is that the human factor plays a (dominant) role in nearly all crashes. This is demonstrated by crash forms drawn up by the police, by crash causation studies and by naturalistic driving studies. Police reports are not a good source to assess crash causation (Hauer, 2020; Shinar, 2007), because the police form is not intended to detect crash causation, but to determine whether a person involved in a crash committed an offence and to contribute to the determination of civil liability.

In the 1970s, two “in-depth” studies were carried out into the causes of crashes, one in the United Kingdom and one in the United States. The results of these two studies (Sabey and Staunton, 1975; Treat et al., 1977) bear many similarities: in approximately 95% of the crashes the human factor was found to have contributed to the occurrence of a crash or to have had an impact on its severity. The road factor had contributed in about 30% of the crashes and vehicle factors were to have played a role in approximately 10% of the crashes. These two renowned studies, carried out by highly respected researchers have very often been cited and seem to “tell the truth.” Now, 50 years later, the results are challenged.

In his article “Crash causation and prevention,” the Canadian emeritus professor Ezra Hauer states that the above results are a “quasi-finding” (Hauer, 2020). In his very readable article, he argues that the results are the consequence of definitions of crash causes which, in his opinion, are unsuitable for crash prevention: “That quasi-finding provided and continues to provide respectability to a style of road safety management that makes the road-user the primary target of prevention actions and obscures the role of legislation, regulation, planning, road design, traffic management, vehicle design, and features in crash generation and crash severity. By so doing the quasi-finding is an obstacle to the transition to the Safe Systems style of road safety management. To support the transition to the Safe Systems style of road safety management a different definition of crash cause is needed. Hauer (and others before him) suggested the following definition: a crash cause is a circumstance or action that, were it different, the frequency of crashes and/or their severity would be different.”

The authors of the tri-level study (Treat et al., 1977) reported that “many human causes may imply the need for changes in vehicles or in the environment.” And, in line with this, Hauer states: “Saying that the human is the sole contributing factor in most crashes misleads the general public and provides succor to those who prefer the old-fashioned road user-oriented crash prevention.” Hauer emphatically links crash cause to crash prevention and this supports current thinking on road safety, the Safe System approach. A basis of this approach is that a crash is rarely caused by one single unsafe action; it is usually preceded by a whole chain of poorly attuned occurrences (Wegman, 2013). This means, as Hauer also argues, that a crash is not just caused by one or a series of unsafe road user actions; hiatuses in the traffic system also contribute to the fact that unsafe road user actions can in certain situations result in a crash. These hiatuses are also called latent errors (Reason, 1990). “Road crashes occur when latent errors in the traffic system and unsafe actions during traffic participation coincide in a sequence of time and place” (Wegman, 2013). The Safe System approach tries to eliminate “latent errors” and to reduce exposure to risk. And secondly, “it aims to make traffic safer by adjusting the environment to the human measure in such a way that people commit fewer errors, and if an error is made, the environment is designed to be forgiving for errors.”

Systematically modifying a road user’s environment by creating conditions that make safe behavior attractive and easy, and unsafe behavior unattractive and difficult is at the heart of the Safe System approach. The key question is how to achieve this in the real world and, more specifically, how to adapt the existing road and traffic environment.

Ezra Hauer’s observations that were introduced above, were in response to a dramatic crash in Saskatchewan, Canada. A bus carrying the Humboldt Broncos hockey team collided with a truck hauling two trailers at an intersection of two rural roads with speed limits of 100 km/h. Both vehicles were driving slightly slower than the specified limit. One of the roads (the one used by the truck driver) had a stop sign. Sixteen boys were killed in the crash. As long as such situations exist, crashes can occur and, unfortunately, will continue to occur. Rewarding or punishing is not the way to tackle road safety problems on intersections such as the Canadian one from a Safe System perspective. In a Safe System, it is made impossible for vehicles to ever collide at such high speeds.

Penalizing, Nudging, Rewarding, and Incentivizing

A dominant activity in road safety improvement is influencing citizen behavior and road user behavior. Traffic education and traffic enforcement (two of the three E’s) are the traditional ways to make behavior safer and to reduce the number of traffic offences. Traffic

offences are associated with a higher crash risk, traffic fines do temporarily reduce risks (Redelmeijer et al., 2003) and traffic enforcement leads to fewer traffic offences and fewer crashes (Elvik et al., 2009).

Influencing behavior does not only involve influencing actual traffic behavior, but also aims at influencing citizens' choices that have—positive or negative—road safety effects: buying a safe car or reducing exposure to risk by choosing a safe route, for example traveling a low risk route rather than the shortest route.

We have several possibilities at our disposal to make traffic behavior safer; they will briefly be introduced here. But first it is important to note that a Safe System approach attempts to prevent road users from running unnecessary risks by eliminating exposure to risk (Wegman and Aarts, 2006). Three examples will illustrate this: (1) adequate median barriers on motorways prevent head-on collisions, (2) driving under the influence of alcohol is prevented by installing an alcolock in a vehicle, and (3) well-located and well-designed speed humps reduce driving speeds and risks.

Enforcing safe conduct through legislation and monitoring is a first option, and will only be effective in reducing risks if legislation is supported by evidence and enforcement is adequate. For example, revoking a driving license is only effective if the driver concerned refrains from driving a motor vehicle. However, if the person concerned estimates that the risk of being fined for driving without a license is minimal and therefore drives anyway, such a measure is not effective. Punishing road users for dangerous behavior and for breaking the law is the first possibility of behavioral influence and will here be called *penalizing*: preventing dangerous behavior by (threatening with) punishments.

A second possibility is *nudging*: this involves moving road users towards safe traffic behavior by supporting them. Traffic-safe choices are offered without making other options unattractive or removing them. Each individual retains his freedom of choice, but subtle influence is used to stimulate a road user to choose safe options.

The third possibility is *rewarding* and *incentivizing*. Rewarding involves rewarding safe behavior. A performance has been achieved (e.g., a million kilometers travelled without being involved in a crash) and the road user is rewarded for this. In the case of incentivizing, a road user is promised a reward and is told which behavior or achievement is rewarded. An incentive should act as a motivation to only engage in safe behavior (e.g., not speeding) or to not be involved in a crash.

Let's discuss the three approaches in some more detail.

Penalizing

There is a long tradition in road safety underlying the idea that traffic behavior is influenced and made safer by using forms of police surveillance. This is a chain approach: legislation—enforcement and punishment. The underlying principles of police surveillance are rather well known: the overall preventative effects of police enforcement are generally greater if the subjective risk of the offender being caught is higher, if the penalty is more severe, if the certainty of a penalty is increased and cannot be escaped, and if the penalty is imposed more rapidly. Each of these elements constitutes a link in the enforcement chain. We have a very long tradition in road safety to work with enforcement on all sorts of risky behavior: speeding, drink-driving, red-light violations, not wearing seat belts, etc. We also learned that the subjective probability of being caught is more important than the severity of the penalty. Penalizing can be done by handing out traffic fines, by withdrawal of the driving license or by giving points in a demerit points system (Van Schagen and Machata, 2012).

Police surveillance operates on the basis of the objective and subjective probability of being caught, and the resulting penalties or measures. Roadside police checks determine the objective probability of being caught, the enforcement pressure. If road users consider the subjective probability of being caught to be sufficient, they will avoid infringements.

Traffic control or police surveillance has proved effective in reducing road risks (Elvik et al., 2009). The effectiveness estimates vary considerably and also depend on the nature of a violation and the extent and nature of the enforcement. Modern technology can assist police in carrying out their enforcement duties, for example, point to point enforcement of speeding or the use of in-vehicle technology (e.g., alcolock or Intelligent Speed Adaptation to influence speed behavior).

Nudging

In their influential book "Nudging" (2008), the authors Richard Thaler and Cass Sunstein present a practical example of influencing behavior by "nudging." They describe the course of Lake Shore Drive along Lake Michigan in Chicago. This road has a number of sharp bends and the city of Chicago tries to increase the attention of road users and to reduce their driving speed (down to 25 mph) with the help of a number of transverse rumble strips that are closer together as a bend approaches. This gives the driver the feeling that the driving speed is going up. This sensation makes road users reduce their driving speed. Thaler and Sunstein (2008) believe that other forms of behavioral influence (legislation and enforcement, public information, financial incentives) are too coercive, too paternalistic, or too expensive. They see nudging as an addition to these traditional forms of behavioral influencing. Of course, the question is whether it is a task for government or road authority to be occupied with influencing traffic behavior, but in many countries worldwide this question has been answered in the affirmative. This is reflected, for example, in the World Health Organization's Global Status Report, which shows that virtually all countries in the world have embarked on legislation and enforcement of safer behavior (e.g., driving under the influence of alcohol, or wearing seat belts). There are, of course, exceptions where the government is accused of paternalism if it were to adopt "restrictions" (such as a number of American States that have not laid down in law a helmet-carrying requirement for motorcycle riders).

The concept of “self-explaining roads” (Theeuwes and Godthelp, 1995) refers to “a traffic environment which elicits safe behavior simply by its design.” Speed behavior plays an essential role in this concept. In addition to eliminating risk to exposure, nudging of behavior (by using road characteristics recognizable for the road user to make road course and behavior of other road users predictable, thereby preventing mistakes and reducing risks) is a cornerstone of the Dutch Safe System approach (Wegman and Aarts, 2006).

Rewarding and Incentivizing

An incentive is a benefit in the form of a good or service for a specific performance intended to increase motivation. Incentives are offered by companies to employees to encourage them to show the desired behavior. Whether and how an incentive works is a careful balancing act. Financial incentives may be considered, but also gifts or outings. In essence, an incentive is a reward that is earned when a certain goal or certain behavior is achieved. Incentives can also be granted to road users to encourage them to achieve the desired level of performance or set goal.

A reward is a benefit that is provided in recognition of achievement, service, commendable behavior, etc. A reward is given to an employee only after he/she has provided evidence of his/her positive behavior and achievements. The aim of a reward is to show the employees that their work and effort are valued, and is given as an appreciation for the work already completed, as well as a motivation to continue improving their quality of work.

Despite their similarities in motivating and encouraging workers to achieve better levels of performance, there are a number of differences between rewards and incentives. The main difference lies in the timelines in which each is offered. A reward is offered after the job has been completed and after the employee has proven his worth. An incentive is offered beforehand and is aimed at improving performance of employees who do not meet expected standards or established goals.

Giving rewards or working with incentives to achieve safer traffic behavior is quite unusual in road safety, however several (small-scale) trials have been carried out in two settings: in companies and when setting insurance premiums.

Examples of Rewarding and Incentivizing in Road Safety

It is quite inconceivable that a total population of road users should be given an opportunity to participate in programs that reward safe behavior in any fashion. Nor are there any known examples. Experience has been gained in rewarding certain groups of road users. We will limit ourselves to two specific groups: road users who participate in traffic professionally and who are in an employer–employee relationship (this will be discussed in further detail in the section *Safety Management in Companies*).

Secondly, there is the relationship between a contractor and a subcontractor. Governments award concessions to public transport companies and a concession can be made to comprise road safety-important elements, including timetable requirements that prevent drivers from being placed under time pressure and thereby prevent unsafe behavior such as speeding.

Another possibility are rewards or incentives that insurance companies can give to their insured. Examples are rewards for having driven damage-free in a certain period and incentives offering premium reduction in the case of no/fewer claims for damages or no traffic violations.

Technological advances allow for monitoring and feedback of driver behavior in an inexpensive manner. In-vehicle telematics or smartphone apps enable drivers, insurers, or employers (commercial vehicles) to collect safety-specific information on a driver's on-road behavior and driving performance and to use this information as feedback to promote safer driving. This certainly made reward and incentive programs more feasible.

Safety Management in Companies

So far, road safety improvement has been strongly based on the idea that mainly the government attempts to contribute to safer traffic behavior and consequently reduce the risks of road users. There are reasons, however, to give the private sector a role (Academic Expert Group, 2019).

Work-related motor vehicle crashes are estimated to contribute at least one quarter to over one third of all work-related deaths (ERSO, 2006). And the relationships employer–employee, and contractor–subcontractor offer influencing-possibilities for safer road traffic, that do not exist in the relationship between the government and the individual road user. An employer can influence behavior in the context of the employment relationship with the employee, by punishing and rewarding. Work-related travel behavior has different characteristics than private travel behavior with private vehicles and it is claimed that the risks of work-related travel are higher than those of private travel. Some evidence has been found, but the variety of work-related trips is immense and there has been no evidence that differences in risk are due to increased risk-taking by, for example, more speeding.

An Australian study (Newnam et al., 2002) even found that work-related drivers were generally more likely to report safer driving in a work vehicle. In particular, it was found that drivers were less likely to commit violations like speeding and driving dangerously in a work vehicle than in their personal vehicle. Additional research should provide clarity on the precise explanations for these findings before drawing conclusions.

In many industrialized countries, a growing number of companies embark upon work-related road safety activities. However, very few programs have been studied (and reported in scientific journals) to establish the effectiveness of the variety of the approaches and measures adopted. This lack of publications complicates drawing firm conclusions.

Based on a literature review, [Haworth et al., \(2000\)](#) identified four areas that have potential to be effective for reducing crashes and injuries (and related costs) by private sector companies: (1) selecting safer vehicles, (2) some specific driver training and education programs, (3) incentives (not rewards), and (4) company safety programs in companies with an overall emphasis on safety. To these four fields of potential activities two more can be added. Making use of technology is another possibility that may be exploited, for example in-vehicle data recorders. Finally, the more recent concept of journey management can be added, a concept developed in the oil- and gas industry with the aim to prevent undesired security HSSE (Health, Safety, Security, Environment) consequences of land transport journeys ([NETS, 2014](#)).

A report "Advancing Road Safety. Best Practices for Companies and Their Fleets" of Together for Safer Roads ([TSR, 2016](#)), a coalition that brings together global private sector companies to collaborate on improving road safety, presents some "best practices" of incentive programs, with names such as Safe Driving Awards, Safe Driving Recognition Programs, the Million Mile Club (of collision-free drivers).

[Haworth et al. \(2000\)](#) were eager to include the results of evaluation studies in their report. But they were disappointed: "There are very few evaluations undertaken, even by best practice companies. Benchmarking is one of the few examples of evaluation, but benchmarking only hints at why some organizations may have lower crash rates or costs than others." Narelle Haworth and her colleagues do come up with a number of conclusions about the safety effects of incentive and disincentive programs reported in the literature: some programs had negative effects, incentive programs (where benefits are conditional upon future safe driving) are more effective than reward programs (where benefits are conditional upon safe driving past. Incentive programs appear to be most effective when the time period in which the desired outcome is expected is in the near future. Incentive programs may be more effective in younger drivers, and drivers with a good driving history who are given a reward either show no difference or increase their crash rate.

NETS, an employer-led advocate for global road safety and a chartered nonprofit non-governmental organization, states that successful road safety programs are resourced, led by leadership and are well-embedded in the line-organization ([NETS, 2014](#)). ERSO suggests that effective road safety programs should be based on an integrated set of data-guided measures based on a strong safety culture within the organization (ERSO, 2007). In other words, both documents argue that programs designed to make road user behavior safer through a system of incentives or disincentives, should be part of a much broader package of measures. But NETS does suggest using incentive schemes to illustrate the importance of these programs: "To reinforce the importance of corporate road safety initiatives, organizations should have incentive schemes in place to recognize good driving behavior and penalize poor performance."

If we look at the results, we can conclude that there is only limited scientific evidence that programs using incentives and disincentives can make a substantial contribution to achieving safety targets in companies. But, incentive programs are rather common in the private sector and positive outcomes are reported by stakeholders.

Insurance Rewards

Many car insurance companies offer a discount on the insurance premium for claim-free driving, also referred to as bonus-malus systems. Insurance companies also differentiate the premium by age, which means that young people (and often novice drivers) pay high premiums. These are not individually set premiums, but premiums set for the group in which someone is classified (age, large city versus rural area). A relationship with a driver's performance due to his own behavior has been abandoned and premium differentiation can therefore not really be considered a reward: own behavior has virtually no influence on the result for the group.

It is, however, reasonable to assume that strengthening the extrinsic motivation of road users by giving rewards or incentives leads to behavioral changes in the desired direction. In recent decades, insurers have focused on premium discounts as a way of influencing safe behavior with fewer crashes (and therefore fewer claims) and a lower damage burden as a result. [Hagenzieker \(1999\)](#) looked at the effects of behavior-oriented rewards and she concluded that few conclusive research results were available ("Some studies investigating the effects of on speed behavior show no conclusive results"). However, there have been developments since then.

A behavior-oriented award approach requires information on driving behavior on an individual level and fortunately modern technology offers a helping hand. First of all, in-vehicle data recorders that are connected to the diagnostic system of a vehicle can also be used to gather information about "dangerous" behavior (speeding behavior, acceleration, cornering, braking, smartphone use, close following, signal use, and brake position (see, e.g., [Horrey et al., 2012](#)). More recently, smartphones are being used to collect information, often linked to special apps (e.g., [Musicant and Lotan, 2016](#)). The first system collects information per vehicle, the second system does so per driver.

In principle, three actions can be carried out with the possibilities mentioned above: the behavior of a vehicle/driver can be monitored, feedback can be given based on the monitoring and, finally, the information collected can be used as a basis for rewarding. Actually, the idea of rewarding safe behavior is not new. As early as 1980, the New Zealand researcher Paul Hurst published a study in which this matter was addressed ([Hurst, 1980](#)).

Research is needed to determine whether monitoring (Hawthorne-effect), feedback or rewarding contribute to the road safety improvement. Experiences during the past 10–20 years have shown that this research is complicated to carry out, that coming to clear conclusions is not so easy, and that generalizing the findings (external validity) is not generally permissible.

As evidenced by a meta-analysis conducted by [Elvik \(2014\)](#), the bottom-line would be, that “most studies involving behavior-dependent (‘direct’) incentives found significant improvements in safety-relevant driving skills.” Measured changes (e.g., in speeding) can be substantial. However, the trials reported in this study included highly motivated drivers and were relatively small. This leads to the question what to expect when scaling up trials. And, is it plausible to expect a (substantial) decrease in the number of crashes and casualties in a country, when applying large scale reward programs?

Carrying out research on reward programs was not without hurdles. First of all, studies should be able to recruit sufficient subjects and the experiences in Denmark, for example, are bizarre. A study could not be carried out successfully because insufficient participants could be found ([Lahrmann et al., 2012](#)). Another problem that arose in an Austrian study, was that participants withdrew from the study ([Peer et al., 2020](#)), which can lead to an attrition bias. A bias due to self-selection could also be a problem, but according to [Peer et al. \(2020\)](#) this was not so much an issue in their research, although [Elvik \(2014\)](#) does not exclude that as a serious problem in these studies.

The next question is which if the factors do in fact explain the positive effects on behavior: is it the monitoring, the feedback or is it the rewards? Research by [Peer et al. \(2020\)](#) shows that all three do have some effect, but that the effects are more pronounced for monetary incentives. This is in line with two other studies ([Mullen et al., 2015](#); [Reagan et al., 2013](#)). It must be noted, however, that these two studies focused solely on speeding offences.

A special type of insurance incentive is PAYD (pay-as-you-drive) in which premiums are directly based on the driving behavior of policyholders. Participants (under 30 years of age) in a Dutch experiment ([Bolderdijk et al., 2011](#)) could earn a €50 reward: €30 was designated as a reward for keeping to the speed limit, €15 was for reduced mileage, and €5 was for not driving during weekend nighttime hours. Their vehicles were equipped with GPS devices allowing for the monitoring where participants were driving, at what speed they were driving and at what time, and how many kilometers they were travelling. The first reward proved to be effective, the other two were ineffective. The researchers concluded that PAYD—as applied in this experiment—leads to modest, but relevant reductions in the driving speed of young adults. If this result is then associated with the “power-law of Nilsson” (small speed changes have substantial effects on crashes/injuries/deaths), these results are promising for road safety.

In conclusion, it can be argued that reductions in insurance premiums provide extrinsic motivation to achieve safer behavior and therefore deserve to be investigated further. They can be applied to all age groups, but young drivers (relatively high risk, relatively high premium) were chosen as target audiences in many studies. An Israeli study ([Musicant and Lotan, 2016](#)) reports that when (young) participants had received the award, they stopped using the app. We also found that the usually small-scale programs required great effort to be organized. This raises the question of the cost-effectiveness of such programs. Furthermore, the extent of the potential range of these programs remains to be seen: the share of road crash casualties to be saved by using insurance rewards.

Key Lessons Learned

A number of guidelines that an effective reward program should meet are presented in a SWOV Fact sheet ([SWOV, 2011](#)). These lessons learned are summarized by Marjan Hagenzieker based on the literature and her own work (1999):

- Clearly inform participants of what they should do to receive a reward and how this is determined; use simple and clear “rules.”
- Avoid giving unexpected rewards to participants that they (could) not have anticipated on in advance.
- Use direct, immediate rewards; these may be supplemented with a lottery system with a chance of a reward.
- Make sure that the participants find the obtainable rewards attractive.
- Be careful with the value of the reward. Rewards need not be great in order to be effective. They should be large enough to induce behavioral change, but not so large that they are the only motivation for the desirable behavior.
- Consider a combination of measures. A reward program is more effective when it is combined with other interventions, such as training or police surveillance.
- Give fast and clear feedback on behavior and improvements with respect to the actual goals. This enforces the effects.
- Repeat the program at regular intervals to achieve also long(er)-term effects. However, reward programs do not need to continue very long to be effective; programs continuing for a few weeks can already be effective to bring about substantial short-term effects. However, repetition is necessary to achieve longer-term effects.
- Monitor the desirable behavior systematically.
- Measure the desirable behavior also prior to the start of the program, not only to set a realistic target, but also to be able to determine the effectiveness afterwards.

Conclusions

In road safety improvement, opportunities have been used in the fields of engineering, enforcement and education for many years; the three E's. Many effective and cost-effective measures are known and are being applied (see, e.g., [Elvik et al., 2009](#)). In many countries, implemented measures have reduced the traffic risks and reduced the number of casualties. The Safe System approach

contains the latest insights on how to make road traffic even safer. Safe System uses “man is the measure of things” as its basis: firstly, people make mistakes that can lead to road crashes and secondly, the human body has limited physical ability to tolerate crash forces before harm occurs.

The Safe System approach tries to strengthen the entire and therefore all components of the road system (human, vehicle, road) and ensures that the road user is still protected even if a component does not function properly. This also means that efforts are being made to eliminate some high-risk elements, such as four-arm intersections outside the urban area with speed limits of 100 km/h, or head-on collisions on motorways. Serious crashes can and will occur at such locations. Finally, not only does a road user have the duty to behave safely, but there is a shared responsibility with responsible road managers, vehicle manufacturers and those who take care of the organization and post-crash quality. This vision does not coincide well with the idea that is often expressed: human error plays a role in almost all crashes and therefore the performance of road users’ needs to be improved by more Enforcement and Education. A very readable article “Crash causation and prevention” by Hauer (2020) supports this idea.

This leads to the question whether giving a reward or promising an incentive for safe behavior fits into the Safe System approach and can make an additional contribution. This chapter answers this question, which also focuses on two other forms of behavioral influence: enforcement and punishing, and nudging. Steering behavior in a safe direction through legislation, monitoring behavior (by the police) and punishing traffic violations is general practice in many countries. There is also a fair amount of knowledge about how to make this effective and each country will need to develop its own chain of enforcement using general knowledge. Of course, there are practical limitations (supervision may be limited, and political priorities for the police may not lie with traffic control), but enforcement should be part of any road safety strategy.

Not as much is known about applying nudging to make traffic safer, but it is a very promising method that has proven its usefulness in other areas. It deserves attention in the development of self-explaining roads in a Safe System approach.

Finally, rewards and incentives. Giving rewards or working with incentives to solicit safer behavior is quite unusual in road safety and evidence of the effects of rewarding in road safety policies is limited. This chapter does include some examples of rewarding safe behavior, in particular rewards given in the private sector and giving discounts on insurance premiums. Occasionally, positive effects are reported, but a guarantee of positive effects cannot be given. The contribution of a reward program to achieving a national target (e.g., 25% fewer deaths in 10 years) is limited, because, as the scientific literature now shows, the scale of reward programs is considerably small. Pilot programs have not been scaled up. It is not evident how to organize large-scale applications of reward or incentive programs. It is not to be expected that replacing enforcement programs, in which dangerous behavior is punished, by programs that reward safe behavior is bringing positive road safety effects. However, the experiences gained with reward programs provide sufficient starting points to draw up a list of “key lessons learned.”

Introduction

Traffic laws must be enforced, to sanction violations and to deter offenders and encourage responsible driving. Enforcement actions target violations like speeding, drinking and driving, not using a seat belt, failing to stop at a red traffic light, use of mobile phones and others. Traditional methods of police enforcement include on-the-spot roadside checks and the use of automated devices such as speed cameras. To be most effective, police enforcement should be publicized, and involve a mix of highly visible and low-profile activities. To maximize the road safety benefit, enforcement should be aimed at road rule violations that have been proven to increase the likelihood or severity of crashes.

Background Theories

3E Model of Traffic Safety

Regarded as a classic model used in traffic sciences, 3E proposes that road users should be perceived from three different points of view: Education and Training, Engineering, Enforcement (e.g., Evans, 2004). If we wish to achieve a real change in road users' behavior (in terms of improving safety or eliminating risky behavior), we need to exert an influence on road users at all the above levels.

Concerning education and training, we need to consider what is referred to as the mechanism of negative effects (Rothengatter, 1981). This mechanism involves the normalization of risky behavior by exposing road users to risk and increasing the level of their acceptance of such risk and their confidence. Engineering primarily involves the planning and implementation of traffic infrastructures and the development of means of transport in such a way as to make them responsive to human needs and nature, as well as promoting the desired safe behavior (Wolshon and Pande, 2016). The concept that is brought up with the greatest frequency in this respect is a self-explaining environment, which should provide intuitive guidance for people as to which behavior is appropriate and safe in a given situation (Kuiken et al., 2012). Another principle involves a forgiving traffic environment, which implies that we need to plan and build the traffic environment in such a way as to ensure that it can offset our mistakes and enable us to learn from such mistakes (Herrstedt, 2006).

The last approach under consideration involves enforcement. It has been demonstrated that this approach to traffic has a positive effect on public health (Tay, 2005; Watling and Leal, 2012), that is effective and fair enforcement influences road users' behavior in terms of reducing their risky behavior. Nevertheless, several preconditions must be met for enforcement measures to be effective. Effective enforcement requires that:

- people know the rules (i.e., they know what behavior is appropriate and expected)
- they must be able to apply their knowledge (i.e., they need to possess the necessary skills and be able to act on their knowledge)
- the benefit derived from breaking the rules must be smaller than the cost of the imminent sanction (i.e., they must be motivated).

The positive effect of enforcement on road safety is an increasing function of certainty (that a person will be sanctioned), strictness (the sanction must have a real impact on a person), and an immediate threat of punishment (a person has no chance of avoiding the sanction) (Armour, 1984).

The Role of Norms and Traffic Safety Culture

Leviakangas (1998) defined the **traffic culture** as a complex of all factors that affect attitudes, skills and behaviors of drivers as well as infrastructure and vehicles. This pushes researchers to think about the definition of term “traffic safety culture”. Edwards et al. (2014) refer to **traffic safety culture** as “the assembly of underlying assumptions, beliefs, values and attitudes shared by members of community, which interact with a community’s structures and systems to influence road safety related behavior.” The traffic culture operates at different levels. It created a background for the multilevel framework, which consists of four levels:

- micro – “individual level factors”;
- meso – “group/community level factors”;
- macro – “national level factors”;
- magno – “ecocultural socio-political level factors”.

Özkan and Lajunen (2011) also proposed the term “**traffic safety climate**” as a way to manifest the traffic safety culture. According to them, it is defined as “road users’ (e.g., drivers, bicyclists, and pedestrians) attitudes and perceptions of the traffic in a context (e.g., country) at a given point in time.”

There are a number of studies, which developed above-mentioned problematics on the cross-national level. The differences among cultures in cases of attitudes toward traffic and risk perception were pointed out by Lund and Rundmo (2009).

Law enforcement—The deterrence theory

The concept of deterrence builds on the notion that “prevention is better than punishment.” Deterrence is, however, never the only or primary purpose of legislation (the legal system). The essence of deterrence is the threat of punishment realized through a certain form of sanction. Deterrence is a way of assuming control on the basis of fear. If drivers commit violations without fearing the consequences, then, by definition, deterrence has no effect on them.

Deterrence generally involves behavioral control, which occurs when a potential perpetrator is not willing to take the risk of engaging in certain behavior out of fear of the consequences (Beyleveld, 1979). Deterrence is thus a mechanism for achieving compliance.

Punishment deters the perpetrator from forbidden behavior, which is considered individual prevention, while also deterring other individuals who might become perpetrators, which is referred to as general prevention. The assumption is that every person knows what is allowed and prohibited, as well as being aware of the possible consequences of illegal conduct. Stafford and Warr (1993) suggest that people’s experience of punishment, both indirect and direct, makes them less prone to violating the rules, as it increases the perception of the risk of punishment. According to the deterrence theory, punishment is considered a means of discouraging perpetrators (including potential perpetrators) from committing violations or offences. The effect of punishment can be divided into several groups.

The first involves the aforementioned theory of general prevention, which is further broken down into negative and positive: the negative theory of general prevention proposes that the threat of punishment will deter the perpetrator from offending. The positive theory of general prevention proposes that strict and unavoidable punishment imposed within a short time of the offence will strengthen confidence in the operation of justice and the national legal system.

The second group is constituted by the theory of special prevention: it is assumed that strict punishment imposed on the perpetrator according to the law will be a sufficient warning for others too.

Another type is the theory of individual prevention. It is based on the idea that the punishment imposed on a perpetrator will cause them harm which will deter them from continuing to engage in illegal conduct without the need for additional remedial measures.

The fourth is the rehabilitation theory. It proposes that a perpetrator’s illegal behavior results from a range of factors (family, upbringing, social circumstances, psychological preconditions, etc.) which influence their conduct and development. The purpose of punishment here is the provision of professional help which will make it possible for the offender to understand their traits, behavior, and the influence of the social environment which led to their offending. The rehabilitation theory seeks to have the perpetrators reintegrated into society on the basis of a change in their behavior achieved by means of their understanding the problematic nature of their previous behavior in the social context (Kuchta and Valkova, 2005).

The final type involves the restitution theory, which highlights the necessity of making amends for the damage and consequences resulting from their unlawful conduct. In these terms, crime is viewed as a threat to society and the damage to the victims it entails.

A Glimpse on Psychological Learning Theory

As human beings are provided with innate behaviors, it is necessary that most of the preconditions for social interactions (e.g., speech, opinions, attitudes) are acquired by experience. They need to be learned. Skinner in his learning theory (1938, 1953) coined the concepts “stimulus” and “response”. In his theory, responses are divided into two classes: reflexes and operands. Reflexes are elicited by stimuli immediately and directly. An example is the pupil reflex: the diameter of the pupil changes automatically with each change of brightness. Operands are arbitrary responses which lead to consequences that are more or less consciously strived for

Table 1 Types of reinforcements and punishments

Reinforcement	1. Positive consequences	2. Nonappearance of negative consequences
Punishment	3. Unpleasant consequences	4. Nonappearance of positive consequences

by the individual. However, they can develop the character of a reflex. For example, if they are regularly connected in time or space to certain situations or circumstances that lead to reinforcement or to negative consequences, those situations or circumstances can elicit such responses in a reflex-like way. To overtake another car according to this definition can be operant behavior. To be faster than the other car is the reinforcement, the car in front is the trigger.

Learning history – for example, frequency of such experiences – determines how strong the degree of automation (= character as a reflex) of the behavior is. The timely distance between the operant and the reinforcement is thereby important for the learning process, it has a strong impact on the speed of learning. The shorter the distance in time, the nearer the reinforcement (or the punishment) to any behavior the faster the learning process. The principles of reinforcement (= facilitation of behavior) and punishment (inhibition of behavior) are of great importance in road traffic. There are lots of rules and there are many legally envisaged sanctions and punishments. Theoretically, there are four different types of reinforcement and punishment (**Table 1**).

Behavioral Interventions - Educational and Therapeutic Measures

Behavioral interventions aim to contribute to the prevention and resolution of behavioral disorders by addressing their causes and determinants. In the context of road offenders, these measures are intended to address the underlying causes that explain the occurrence of inappropriate or deviant driving behaviors. Whether or not they apply to the context of road traffic offenses, the development of such interventions must be based on specific measures and fundamental principles. In the context of traffic offenses, three functioning components turn out to be of major importance:

- Principle of risk: it refers to the prediction of the repetition of a risk for a specific person. The principle implies that the intensity of an intervention must be proportional to the risk of repetition.
- Principle of need: it is relevant for the determinants of an offense (road) behavior. On the basis of this principle, effective interventions target the factors associated with transgressive behavior.
- Principle of the answer: it refers to the probability of a good answer from a specific person. According to this principle, the design of the program must be consistent with the skills, abilities and motivation of the participant.

Educational and/or therapeutic measures are one of the possible forms of “punishment” for traffic offenders. These are generally part of a legal context, most often for severe traffic offences, and can be imposed on offenders either in addition to or instead of a “traditional” sanction (i.e., withdrawal of driver’s license, fines imprisonment) or even to reduce its heaviness. For example, educational intervention may be imposed as a necessary condition to recover the driver’s license after withdrawal.

The presupposition of such measures is threefold: (1) driving is in essence a ‘learned’ behavior and can therefore be modified and influenced; (2) traditional punishments (e.g., fines or withdrawal of driver’s licenses) are not always sufficient to lead to behavior change; (3) these measures are necessary to restore driving ability in completeness driver’s assessment (Panosch, 2001).

Conceptually, taxonomy based on the level of empathy has identified four profiles of drivers at risk (Brion et al., 2018):

1. Anti-social drivers: the lowest level of empathy and not understanding the consequences of their behavior.
2. Careless or ignorant drivers: ignore the needs of others even if they are capable of empathy; drive irrespective of other road users but are in principle sufficiently skilled to drive safely.
3. Drivers in search of risk-taking: has a good level of empathy but has a poor ability to assess risks and drive for the excitement and fun that the road gives them.
4. Unskilled drivers: Has a good level of empathy but the level of risk is determined by limited experience, functional limitations or physical vulnerability. This group consists of older drivers, drivers with some disease, healthy drivers with an anxious driving style or those who are not assertive enough and cannot withstand social pressure, but also of young drivers with still low experience level.

Implications in Road Safety Work

In practice, above-mentioned theories become interlinked in such a way as to ensure that traffic-related sanctions meet the objectives of a national punitive policy to the effect of protecting the public, resocializing the offender, making amends for damage caused, and deterring potential perpetrators.

Traffic Law Enforcement is Usually Punishment

From a pedagogic point of view, positive reinforcement is a useful method to enhance wished-for behavior. However, it is difficult to implement in road traffic. Punishment functions, as well, but tends to have negative side effects (Schlag, 1995). For instance, it is

problematic that by providing negative consequences you stop nondesired behavior, but if no help is given, no alternative behavior will develop. The resistance of any behavior, enhanced by punishment, toward extinction is lower compared to reinforcement: the behavior is no longer carried out when nondesired behavior is not followed by punishment. Well-known examples include what happens when a speed measurement radar is taken away or when the alcohol-interlock period of an infringer ends: The probability that the nondesired behaviors—speeding, driving under the influence of alcohol—appear again when there is no more punishment is high.

Moreover, punishment can cause anxiety, or reactance towards those who punish. Such effects would imply that people do not want to learn anything from the punishing institution; for example, you don't want authorities to tell you what to do. Especially hard punishment can also cause aggression, which of course is not supporting traffic safety.

As far as police work is concerned, up to now no effective models of systematic positive reinforcement have been found that would work in connection with law enforcement on the road.

What to Consider When Applying Punishment (Fines)

The conclusion is not to have a traffic law enforcement system without punishment. Rather, it is important to consider some aspects in connection with the application of punishment (see e.g. [Zimbardo and Ruch, 2013](#)):

- Punishment should be provided in a way that it cannot be avoided (it should be *consequent*)
- Punishment should follow immediately after the behavior (it should be *contingent*). A fine several weeks after speeding does not provide any relationship of the punishment (= the fine) to the nonwished for behavior.
- Until the desired behavior is *internalized* (= is carried out habitually) punishment should follow after every erroneous behavior as far as possible (it should be *consistent*).

In sum, one has to punish consequentially, contingently and consistently in order to make the relation between nondesired behavior and fine clear and to keep it that way. But some other conditions should be fulfilled, as well:

- The punished person should be able to understand the reason for the punishment. There should be enough problem awareness to understand why to avoid the nondesired behavior.
- It is necessary that the punished persons trust in the authorities (and vice versa).

Awareness Raising/Campaigning as a Complement to Police Enforcement

To reach these later goals societal development of a certain status of awareness is needed. In this connection, awareness raising with the help of arguments and facts has turned out to be a most important complement to law enforcement measures in traffic. Not least, meta-analyses have shown that law enforcement is efficient when systematically and professionally combined with traffic safety campaigns (e.g., [Aamodt, 2004](#); [Elvik, 1997](#); [Elvik, 2016](#)). Among other things, public institutions and decision makers, supported by the media, need to display problems connected to road traffic and to mobility in an objective and evidence based way. For instance, one needs to make it clear that traffic is a system where one's own behavior has impact on others and vice versa and such a system can only work if one respects other road users. Constitutional law concerning human rights would support such an approach ([Eisenberg, 1986](#); [Halmetschlager, 2008](#); [Popper, 1971](#)). The interests of other persons are always connected to the consequences of one's own behavior as a road user, especially as a motorized one. Thus, prosocial behavior needs to be argued for, among other things.

Reinforcement in Addition to Law Police Enforcement

Even if it is difficult to envisage an enforcement system applied by the police that uses positive reinforcement, such measures can be—and are—applied by employers, or by insurance companies. [Schade et al. \(2003\)](#) mentioned the Swedish Televerket study by [Gregersen et al. \(1996\)](#) where the effectiveness of four different interventions (driver training, group discussion, information campaign, bonus program) was analyzed. Four groups that underwent such measures were compared to a control group without measures. All four groups, but not the control group, showed improvements concerning accident frequency and accident costs. The best results could be found in the groups "discussion" and "training."

Other types of reinforcement are bonus-malus systems as applied by insurance companies. Drivers who did not get involved into traffic accidents over a certain period of time do receive a reduction of their insurance fees, while involvement in accidents leads to an increase of the fee. A reduced fee can be raised again, if there is accident involvement again, and the malus can be cancelled, leading to a reduction of the fee, if no accident involvement was given for a certain period of time.

Table 2 shows examples of the four different types of reinforcement and punishment (**Table 1**) that are relevant in connection with traffic safety. Only the unpleasant consequences refer to traffic-law enforcement in the narrow sense:

Does the Size of the Fine Matter?

The impact of the size of the punishment is assessed as being low as [Björnskau and Elvik \(1992\)](#) and [Elvik and Christensen \(2007\)](#) could show. In the analysis of 2007, higher fines led to slightly positive effects concerning belt use. But the authors conclude that

Table 2 Types of reinforcements and punishments

	<i>Positive consequences</i>	<i>Unpleasant consequences</i>
Following the behavior	Reinforcement: e.g. lower insurance fee after one year of driving without accidents	Punishment: e.g. fine after an infringement; higher insurance fee after accidents
Removed after the behavior	Indirect reinforcement: removing an insurance malus after years of driving without accidents	Indirect punishment: withdrawal of driver's license; removing an insurance bonus

there was an overlap effect by the campaign to wear seat belts that was carried out at the same time. Concerning speeding, higher fines had low effect. The explanation usually is that the probability to get caught is much too low. The point of view that mainly the subjective assessment of the probability to get involved into an enforcement and punishment measure is relevant for law abiding behavior is supported by [Schlag et al. \(2012\)](#).

Demerit Point System and Driver Rehabilitation

Point demerit systems are a much-debated topic in the traffic context. In addition to commenting on general issues concerning appropriate ways of addressing drivers' transgressions, traffic psychologists engage in frontline work with those whose driving licenses were suspended as a form of punishment. Because of their improper traffic behavior, such drivers are required to undergo a special psychological assessment before they can have their license reinstated. During the assessment for psychological fitness to drive, the psychologist should determine whether the driver has learnt their lesson from the punishment. Interestingly, those drivers who had lost all their points in particular were found to show less sensitivity to punishment ([Goodwin et al., 2013](#)). It is essential to recognize, however, that no psychological assessment in itself will make a person a better driver. Other follow-up interventions and rehabilitation programs need to be embarked upon. Sanctions alone do not necessarily result in what is hoped for, the long-term rectification of risky or aberrant traffic behavior. The issue of reoffending is associated with the absence of insight into the hazardous nature of one's own behavior, the adverse arrangement of personality traits, and rigid attitudes toward road safety. A certain group of drivers sees punishment only as a warning which they ignore or cannot change their behavior to comply with. This is where rehabilitation programs may be useful in providing help to those risky drivers who are seeking to change their behavior and avoid repeating their previous mistakes in the future ([Sucha et al., 2013](#)).

Recommendations for the Effective Enforcement in the Road Safety Domain

Based on the large scale European research project ESCAPE ([Mäkinen et al., 2002](#)), we conclude the following recommendations for the effective enforcement in the road safety work:

- There is wide-spread support for enforcement among the public.
- The mechanism of enforcement is based on deterrence. Ample empirical evidence show that the deterrence principle works in experiments. Enforcement based on deterrence is cost effective.
- Enforcement needs can be crudely classified into three groups: (1) old priority areas all nations share: alcohol, seat belts, speeds; (2) special needs of individual nations, and (3) new needs: e.g. cross-border traffic, illicit drugs, road rage.
- Drink driving enforcement shows that long-term, durable and combined methods (high risk of detection, education, information) bring about good results.
- There is no proof that severe punishments are effective in suppressing reckless driving.
- Interference by the police is important in influencing speeds; perhaps more important than severe punishments.
- The need for massive deterrence-based enforcement systems targeted to catch as many offenders as possible may be questioned; it is a sign of disintegration of the transport safety system.
- The possibilities of enforcement do not reside in enforcement itself, but in integrated traffic safety work; the road infrastructure should be improved as far as possible.
- Enforcement is not solely the responsibility of the police; rather a division of enforcement responsibilities between different authorities is needed.
- Improvement of in-vehicle technology (intelligent speed adaptation; lateral and longitudinal support systems) decreases the need for enforcement in the long run.

Epidemiology and Scope

Epidemiology can be defined as the study of how often diseases and health issues occur within the population and the reasoning of why these events occur. Epidemiologists study disease and health problems in many disciplines, including in the area of road safety. Serious injuries and fatalities resulting from road traffic crashes are a major public health issue that has attracted intensified global attention since the United Nations declared a Decade of Action for Road Safety (2011–20). As reported in the most recent Global Status Report published by the World Health Organization (WHO) (2018), road crashes result in 1.35 million fatalities each year and between 20 and 50 million injuries. In 2016, road injuries were reported to be the 8th leading cause of death worldwide (ranked 10th in 2000). For the same year, road crash-related injuries were reported as the 8th and 10th leading cause of death, respectively, for upper-middle-income countries and low- and lower-middle-income countries. The road trauma burden falls disproportionately across the globe—deaths are disproportionately higher in low- and middle-income countries (LMICs) than in high-income countries (HICs), in relation to population levels and size of vehicle fleet. The rate of road traffic fatalities for low-income countries (LICs) is 3 times higher than the rate of HICs. More specifically, for LICs there is an average of 27.5 deaths per 100,000 population compared to an average of 8.3 deaths per 100,000 population in HICs (WHO, 2018). Socioeconomic status has also been shown to affect road traffic deaths, with individuals from low-income classes, irrespective of country, more susceptible to road traffic deaths than those from high-income classes. In addition, the WHO (2018) reported that worldwide road injuries are the leading cause of death for individuals aged 5–24 years. More specifically, the proportion of deaths from road injuries for people aged 5–29 years is 12.5%. Further, male road users are more likely to be involved in road crashes when compared to female road users.

A broad range of policies and programs have been introduced in an effort to reduce serious injuries and fatalities associated with road crashes. Notably, at the global level, the United Nations Decade of Action for Road Safety 2011–2020 was initiated in March 2010 by the United Nations General Assembly. This global movement aimed to first stabilize, and then reduce, forecasted levels of fatalities across a 10-year period. The Decade of Action for Road Safety 2011–2020 strategy had the ambitious target to halve the number of projected road deaths by 2020 (from 2010). In order to achieve this target, countries were encouraged to implement activities within their own national road safety strategies which aligned with five pillars: Pillar 1: road safety management, Pillar 2: safer roads and mobility, Pillar 3: safer vehicles, Pillar 4: safer road users, and Pillar 5: postcrash response. The Decade of Action has produced some important momentum and has increased global attention and efforts to reduce injuries and deaths on our roads in many countries. Yet, more needs to be done, as evidenced by the information contained in the recent 2018 Global Status report.

There is substantial variation in road trauma among various road user groups according to country-level income. Generally, road traffic crashes in HICs are more likely to involve drivers, whereas in LMICs, vulnerable road users, such as pedestrians and riders of motorized and nonmotorized two and three wheelers, are overrepresented in the crash data. Given the differences in road safety-related challenges across low to HICs, this article discusses the behavioral risk factors associated with road traffic crashes for these countries separately. First, this article will discuss the five of the leading high-risk behaviors reported to account for a large proportion of injuries and deaths in HICs. These five risk behaviors include speeding, driving while impaired by alcohol and drugs, not wearing

a seat belt, fatigue (drowsy driving), and driver distraction. It is acknowledged that not wearing a helmet on motorcycles is an additional risk factor. However, and given that helmet rates for motorcycles have increased substantially, to a point where in most HICs it is now not considered a major risk factor, this behavior is not discussed later. Next, this article will discuss approaches which have been implemented to change driver behavior, including road safety strategies, legislation and enforcement, and public education, advertisement, and mass media campaigns. This article will then discuss main human behaviors that account for the road traffic crashes in LMICs and present some of the road safety initiatives which have been introduced to reduce fatalities and injuries in these countries. It is acknowledged that factors other than human behavior contribute to road traffic crashes (e.g., road infrastructure, vehicle type and condition, and weather conditions). However, a fuller discussion including nonbehavioral factors is beyond the scope of this article.

Road Traffic Crashes—High-Income Country Context

Five Behavioral Risk Factors Which Contribute Significantly to Road Deaths

Five behavioral risk factors that contribute substantially to road deaths include speeding, driving while impaired by alcohol or drugs, seat-belt use, fatigue, and driver distraction (Fig. 1). Speeding refers to exceeding the posted speed limit and has been shown to increase both crash risk and crash severity. Even a low-level speeding (e.g., 5 km/h over the posted speed limit) can increase a driver's risk of being involved in a crash. While research has shown that drivers are aware of the risks associated with speeding, speeding behavior still remains relatively socially acceptable and commonplace in HICs, even those where speed-management countermeasures have been in place for decades. Driving while impaired is another behavior shown to increase crash risk. Alcohol consumption and drug use have both been shown to significantly impair cognitive and motor abilities and have negative effects on driving performance. For instance, alcohol can reduce the drivers' ability to judge speed and distance, increase drivers' reaction time, and impair vision. While driving under the influence of alcohol or drugs is generally less socially acceptable than speeding behavior, alcohol- and drug-impaired driving crashes remain prevalent.

Seat belts have been shown to significantly reduce injury severity that might be sustained in the event of a crash. Seat belts were first introduced into vehicles from 1959, and were made compulsory between the 1970s and 1990s. Since the introduction of

Speeding	• Refers to driving at a speed that exceeds the posted speed limit. • In 2016, 27% of fatal crashes involved at least one driver who was speeding in the United States.
Driving while impaired by alcohol and drugs	• Driving while impaired by alcohol refers to driving when over the legal blood alcohol concentration (BAC) limit of 0.08g/100mL. Driving while impaired by drugs refers to driving while under the influence of prescribed illicit drugs. • In 2016, 28% of fatal crashes were associated with alcohol-impaired driving in the United States.
Seat belts	• All occupants of passenger vehicles are required to wear appropriate an restraint (e.g. seat belts or child restraint) • In 2016, 44% of fatal crashes in the United States involved occupants who were unrestrained at the time of crash.
Fatigue	• Fatigue refers to driving while tired (also referred to as drowsy driving). • The NHTSA estimates 100,000 police reported crashes involved drivers who were driving while tired each year. However, it is thought that this number is higher.
Distraction	• Driver distraction refers to any activity that takes the drivers attention away from the driving task. • In 2016, 3450 people lost their lives while distracted behind the wheel in the United States (9.2% of total road fatalities).

Figure 1 Five risk factors which contribute to road deaths based on data from the United States (NHTSA, 2017).

seat-belt law—which requires all vehicle occupants to wear seat belts—seat-belt use has been steadily increasing. From the mid-1970s/1980s in Australia, later in the United States and Europe, child restraint safety laws were also introduced requiring children under a certain age to use an approved child restraint or booster seat.

The next behavior, fatigue or driving while tired, has been shown to reduce vigilance and alertness and, as a result, leads to a decline in driving performance. The behavioral outcome of driving while tired has been reported to be similar to that of driving under the influence of alcohol. For instance, it has been reported that being awake for 17 h is equivalent to having a blood alcohol concentration (BAC) limit of 0.05 g/100 mL. However, and unlike the other behaviors discussed in this section, there are no current laws that regulate driving while tired except for heavy vehicle drivers (i.e., trucks, buses, and coach drivers) in some countries.

Finally, driver distraction refers to any activity that may take the drivers' attention away from the road (e.g., eating and drinking, talking to passengers, and phone use). In a vehicle traveling at 100 km/h, a driver who takes their eyes off the road for 2 s will have driven over 50 m without awareness of what is occurring in front of them. The focus on driver distraction has increased in recent years with the introduction of smartphones (Oviedo-Trespalacios et al., 2016). Smartphones can result in the following distractions for drivers: visual distractions (i.e., a driver is looking at their smartphone rather than motoring the road environment), physical distractions (i.e., a driver is required to take a hand off the steering wheel to access their phone), and cognitive distractions (i.e., a driver's attention is directed away from the road environment). Further, it has been estimated that drivers who use a smartphone anytime while driving are 4 times more likely to be involved in a crash compared to those drivers who do not use a smartphone when driving. The last two behavioral risk factors discussed earlier (i.e., driving while fatigued and distracted driving) are notable in that they pose specific challenges for law enforcers, making these behaviors difficult to manage.

Encouraging Safer Road Use

The following section of this article focuses upon countermeasures that have been implemented to improve road user behavior. These approaches include (1) road safety strategies, (2) legislation and enforcement, and (3) public education, advertisement, and mass media campaigns.

Road Safety Strategies

A large number of HICs have implemented national strategies aimed to reduce serious injuries and road crashes. The National Road Safety Strategy (2011–20) in Australia, New Zealand's Safer Journeys, Vision Zero from Sweden, Sustainable Safety from the Netherlands, and the European Commission: Strategic Action Plan on Road Safety are some examples of strategies which have been introduced to improve road safety. These strategies are based on the safe system approach to improving road safety. The safe system approach acknowledges that human error will continue to contribute to road crashes, but these errors should not cause serious injuries or deaths of road users. The safe system approach acknowledges that a crash can be the result of a combination of factors and, as such, consists of four main elements including safe roads and roadsides, safe speeds, safe vehicles, and safe road use. In other words, responsibility for road crashes is shared between all system designers and users, rather than the traditional approach that focused only on laying blame on the road user.

Legislation and Enforcement

As highlighted in the WHO's (2017) Save LIVES Technical Package—a compendium of evidence-based road safety countermeasures—legislation is a necessary and effective intervention to reduce road crashes and related trauma. Importantly, for legislation to be effective, it must be coupled with well-resourced, sustained enforcement activities that can assist with attitudinal, social, and behavioral change over time. In relation to the risky behaviors discussed earlier, legislation and various enforcement techniques have been implemented in various HICs to manage and reduce speeding, limit the amount of alcohol and drugs present while operating a vehicle, increase seat belt and child restraint use, and reduce driver distraction. Some examples of legislation and enforcement approaches for each of these behaviors are briefly discussed later.

Speed limits vary within and across HICs. For example, a default urban 50 km/h speed limit applies in Australia, whereas on highways the maximum speed limit is typically 110 km/h, with some state-based variation. In the United States, minimum speed limits may also apply on some roads, such as highways, and in the United Kingdom, some local authorities have adopted a 20 mph (32 km/h) speed limit for residential and urban streets. In France, there are two sets of speed limits: one that applies in dry weather and a lower speed that applies in wet conditions. A range of speed-management strategies, including speed enforcement, is used to encourage compliance with speed limits. Speed enforcement strategies vary, and can include the overt and covert use of fixed, mobile and section control/average speed cameras. Research has shown that speed cameras and appropriately administered related penalty regimes are effective in reducing speed-related crashes and associated fatalities and injuries. The use of intelligent speed adaptation (ISA) technology is increasingly being considered to assist in managing speeds, and a recent development in Europe indicates that all new models of cars sold in the European Union by 2022 will need to be fitted with ISA.

As noted earlier, driving under the influence of alcohol and drugs increases crash risk. As such, many HICs set and enforce strict BAC limits for drivers of light passenger vehicles and a zero BAC for novice and commercial drivers. BAC limits vary across countries. For example, in Australia and New Zealand the legal BAC limit is 0.05 g/100 mL for drivers who hold an open

(unrestricted) license (Australia) or for drivers 20 years and over (New Zealand). The legal BAC limit of 0.05 g/100 mL also applies to those who had a standard drivers' license in many European countries (range BAC limit of 0.00 g/100 mL–0.08 g/100 mL). In almost all of the United States and Canada, the legal BAC limit is higher, at 0.08 g/100 mL for drivers aged 21 years and older. Enforcement strategies differ across countries, primarily based on legislative power of enforcement agencies to stop and test a road user for the presence of alcohol, without direct evidence of impairment. In some jurisdictions, police are able to conduct random breath testing (RBT) which means a vehicle can be stopped at any time and the driver breath tested, without any suspicion of impairment. RBT has operated successfully in New Zealand, Australia, and some European countries (e.g., Finland and Sweden). Compulsory breath testing (CBT) is a different enforcement strategy, where all drivers who stop at CBT checkpoints are required to be tested for alcohol use. This enforcement technique is used in countries such as New Zealand. Another enforcement strategy gaining in popularity in some HICs is the legislated use of alcohol ignition interlocks, especially for recidivist offenders. An interlock device can be installed in a vehicle and is essentially a breathalyzer for individual vehicles that requires the driver to provide an alcohol-free breath sample or the vehicle will not start. Interlock devices are already prevalent in commercial vehicles in some HICs, compulsory for repeat offenders in others, and could also be mandated by the European parliament for all new vehicles from 2022. Enforcing the presence of drugs, however, is a more complicated enforcement issue when compared to alcohol. It is illegal in some HICs for drivers to drive under the influence of impairing drugs. This law includes both illicit drugs (e.g., methamphetamines) and prescription medications, which can be purchased over the counter at local pharmacies or drug stores. Similar to RBT, random roadside drug testing is one type of countermeasures used in countries, such as in Australia, to test for illicit drug use by drivers.

Legislation for the compulsory wearing of seat belts was introduced in many countries in the 1970s–90s. While there was some criticism of seat belts when they were first made mandatory, today there are high seat-belt wearing rates amongst drivers and passengers in many HICs. In Australia, the United Kingdom, and New Zealand, seat-belt rates are above 90% for drivers and passengers. Seat-belt usage rates in the United States differ by state; however, and similar to Australia, the United Kingdom, and New Zealand, has risen since the 1980s. While seat-belt use is mandatory for light vehicles, in some countries, seat belts are not required for bus occupants (unless seat belts are already installed in the bus). In addition to seat belts, child restraint laws have also been introduced in many HICs. Child restraint legislation states that it is mandatory for all children to wear an approved child restraint. The type of restraint differs based on the child's age/height, for example, and in Australia, rear-facing restraints for babies up to 6 months of age or booster cushions for children aged 4–7 years of age. Similar to adult seat belts, child restraints have been shown to reduce injuries and deaths associated with traffic crashes.

While it is important to note that driver distraction includes any activity which may distract from the driving task, more recently, the focus has been on distraction caused by mobile (cell) phone use. Given that mobile phone use is rated as one of the top driver distractions, many countries have introduced legislation that bans the use of handheld mobile phones while driving. Further, a number of countries, including France and Spain, have applied the legislation to ban the use of taking phone calls through Bluetooth headsets. For some states in Australia and the United States, novice drivers are also prohibited for using a mobile phone while driving. Despite the introduction of legislation that prevents mobile phone use while driving, many drivers still report using their phone to text, call, or engage in other online activities (e.g., social media or checking emails). Enforcement of phone use while driving can be difficult, especially if phones are used in a concealed manner, i.e., a driver hides their phone on their lap or underneath the steering wheel. Phone applications and functions, for example, the iPhones' "do not disturb while driving" function, can be used to block incoming text messages and phone calls; however, this technology relies on the driver installing and using this technology while driving. Handheld mobile phone use while driving is difficult for police to enforce. Unlike other illegal behaviors, which use camera technology, for example, speed cameras, the primary detection method used by police for handheld mobile phone is visual detection.

Compared to speeding, driving while impaired by alcohol, seat-belt use, and driver distraction, limited legislation and enforcement strategies have been introduced to combat driver fatigue. In some countries, there are fatigue-related heavy vehicle laws that prevent drivers from operating a heavy vehicle while fatigued. In Australia, for instance, work time and rest time are required to be counted in order to prevent fatigue. Further, drivers who operate heavy vehicles and who drive more than 100 km from their base are required to keep a work diary to record their work and rest breaks. For people with untreated sleep disorders, driver license restrictions may also apply in some countries. Compared to the other behaviors, driving while tired is difficult to assess. For instance, while there are speed cameras to determine speed and breath/blood testing to assess alcohol/drug impairment, there are no objective measures to assess driver fatigue. Technologies, such as using an in-vehicle camera to track eye movement activity, are currently being used in studies to assess drowsy driving. However, these technologies are not yet widely available.

Public Education, Advertisement, and Mass Media Campaigns

Public education, advertisement, and mass media campaigns are additional countermeasures used to promote safe road user behaviors. Advertisement and mass media campaigns can be used to publicize changes in legislation and/or penalties, support enforcement and advocacy activities, and to educate drivers on the negative consequences associated with risky and/or illegal behaviors and the positive consequences of safe road use (Lewis et al., 2019). In Australia, for instance, mass media campaigns were instrumental in promoting the introduction of RBT in the 1980s by highlighting that motorists could expect to be stopped and breath tested for the presence of alcohol anywhere and at any time (Cameron et al., 1993). Since then, sustained media campaigns have been used to reinforce this message. More recently, road safety campaigns have been used to promote other safe behaviors used

to protect vulnerable road users. For example, the minimum passing distance rule of 1 m (or 3 ft.) when passing a cyclist or to remind drivers of the reduce speed limits around schools when children are often seen entering or leaving the school grounds.

Road Traffic Crashes—Low- and Middle-Income Country Contexts

As noted earlier, road traffic deaths are disproportionately high in LMICs when accounting for population levels and size of vehicle fleet. The most recent WHO Global Status Report on Road Safety (2018) notes that no LIC has experienced a reduction in road-related deaths since 2013. LICs have the smallest proportion of motorized vehicles (1%) but account for 13% of global fatalities. In middle-income countries (MICs), the burden is proportionately greater—with 59% of the global vehicle fleet and 80% of global road deaths. When compared to HICs, there is also variation in the types of road users most affected by road trauma. In HICs, vehicle occupants are predominant. However, in the LMIC context, it is vulnerable road users such as motorcyclists, pedestrians, and cyclists who are overrepresented in road crashes. Further, and in LICs, young children are more likely to be involved in road crashes as vulnerable road users than children in HICs. Some parts of Asia and Africa have been, or are, experiencing dramatic increases in motorized two- and three-wheeler forms of transportation: a situation that brings unique challenges rarely faced in HICs to date. Regulating the safety standards of such vehicles, as well as regulating and enforcing their safe use on the road requires resources and systems that may not be available (e.g., a robust rider licensing system, sufficient political will to enforce laws when authorities recognize that to limit use of such vehicles would prohibit individuals from earning an income).

Countries in Africa have the highest rate of deaths (average of 26.6 deaths per 100,000 population), followed by countries in Southeast Asia (average of 20.7 deaths per 100,000 population) (WHO, 2018). In some countries in Africa, walking is the most common form of transport. In many cases, limited facilities are available for pedestrians to safely negotiate their interactions with motorized vehicles. Therefore, it is not surprising that pedestrians (the least protected road user group) are overrepresented in crashes. By comparison, in Southeast Asia, there are a higher proportion of deaths involving motorcyclists (compared to deaths involving other road users), because motorcycles are more common on the roads and are often the main family vehicle that must carry a large number of family members at one time. In LMICs, more evidence-based, best practice legislation covering key behavioral risk factors is needed. Importantly, it is not only the LMICs that must improve in this regard. Unfortunately, the most recent Global Status Report on Road Safety (2018) reports that only five countries have best practice laws for speeding, driving while impaired by alcohol, the use of helmets for motorcycles, and the use of seat belts and child restraints. This result signals the need for urgent legislative attention in almost all nations.

In the LMIC context, even when legislation is present, a lack of compliance is commonplace, as are lower levels of police enforcement and less public education, advertisement, and mass media campaigns compared to what has traditionally occurred in many HICs. As such, road users may be more likely to engage in on-road risk taking behaviors, possibly because they perceive that they are unlikely to be caught by police or because they are not aware of the risk of harm they face. These behaviors include, but are not limited to, not wearing motorcycle helmets, illegal crossing behaviors or walking on roads (due to a lack of footpaths), speeding, alcohol impaired walking and driving, drug driving, and fatigue (due to walking longer distances rather than operating a vehicle when tired). Driving under the influence of drugs is also likely to be a contributor to road trauma, although prevalence is difficult to determine due to a lack of testing regimes (the 2018 Global Status Report indicates that only 75 countries reported conducting some level of drug testing among fatally injured drivers). In addition to these risky behaviors, and compared to HICs, there is less access to appropriate and timely emergency services and medical treatment. It is well known that individuals have the greatest chance of survival if treatment is received soon after a crash. A lack of availability of adequate first response and specialized medical treatment in LMICs therefore contributes to their disproportionate representation in the global road trauma data.

Road Safety Programs and Initiatives in Low- and Middle-Income Countries

In recognition of the need for dramatic and ongoing improvements in road safety performance of LMICs across a range of issues (e.g., legislation, infrastructure, and enforcement), a number of multicountry programs have been implemented to address key road user behaviors, including the Child Health Initiative, the Botnar Child Road Safety Challenge, and the Bloomberg Philanthropies Initiative for Global Road Safety.

Legislation and Enforcement

Some of the programs listed earlier focus on strengthening risk factor-related legislation to align with best practice. The 2018 Global Status Report shows that some progress is being made on this front. For instance, since the 2015 report, 22 countries had improved laws to align with best practice recommendations for speeding, driving while impaired by alcohol, and the use of helmets, seat belts, and child restraints. However, the report also noted that the presence of best practice laws covering these five behavioral risk factors was more common in HICs than in LMICs. As a signal of just how much improvement is still required in high-, middle-, and low-income contexts, only five countries were reported as having evidence-based legislation on all five of these behavioral risk factors.

If each risk factor is examined separately, we see the same pattern according to country income status (WHO, 2018). For example, in regard to speeding, best practice laws were more common in HICs (50%) compared to MICs (37%) and LICs (13%). For driving while impaired by alcohol, best practice laws were again more common in HICs (58%) compared to MICs (40%) and LICs (2%). For

motorcycle helmet laws, 167 countries that had mandatory helmet laws for motorcyclists, 49 were identified to have best practice seat-belt laws. Even though LICs have a higher prevalence of motorcyclists when compared to HICs, of those 49 countries which met best practice, only 6% were LICs. For seat belts, of the 161 countries which had seat-belt laws, 105 were identified to have best practice seat-belt laws, with only 7% of those 105 countries meeting best practice were LICs. For child restraints, 84 countries had child restraint laws, and 33 of those countries met best practice. However, of those 33 countries, no LIC had child restraint laws that met best practice (WHO, 2018).

Enforcing legislation is a challenge in the LMIC context for a number of reasons. In some cases, no penalty provisions are present which can lead to reluctance on the part of police to enforce the law because they are unable to give a sanction to offenders to deter reoffending. In other cases, laws contain specific information about equipment quality standards (e.g., helmets or child restraints) but no provision is made regarding the agency with responsibility to monitor and enforce such standards. Other challenges can include a lack of political will to enforce the law because of public disapproval as well as limited enforcement resources (e.g., personnel and equipment) and a lack of technical expertise.

Public Education, Advertisement, and Mass Media Campaigns

Since road safety is relatively new on the agenda of many LMICs, the use of road safety awareness raising campaigns, compared to what has occurred in many HICs, is not as extensive. Initiatives have tended to focus on public education in schools as well as limited mass media communications about the risks of a particular behavior. There is a significant need to align communications so as to link awareness raising about the behavioral risk factors with police enforcement activities. Experience from the HIC context has consistently demonstrated that enforcement and education campaigns need to work together to obtain maximum road safety benefits. Given the aforementioned challenges in enforcement in LMICs, coupled with limited resources for road safety advertising, there is need to improve this aspect to improve road safety outcomes.

Summary and Concluding Comments

This article has discussed some of the human-related factors associated with traffic crashes in HICs and LMICs. It has been highlighted that various approaches including road safety strategies, legislation and enforcement, and public education, advertisement, and mass media campaigns have been effectively implemented to reduce crashes associated speeding, driving while impaired by alcohol, not wearing seat belt, driver distraction, and fatigue in HICs. It was also noted that in LMICs, while vulnerable road users are at greater risk on the roads, there is a lack of evidence-based best practice legislation for key behavioral risk factors, less compliance with road rules and limited enforcement, and a lack of public education advertisement strategies compared to HICs.

Knowledge in understanding the factors associated with road crashes is advancing. Epidemiology, which starts with looking at injuries or fatalities on a per capita basis, is an efficient way of identifying sectors, areas, or geographic regions with high risk per 100,000 people. In a road safety context, epidemiology assists with identifying the causes associated with injuries and fatalities resulting from road traffic crashes. Recently, researchers have applied a process referred to as data linkage in order to gain a greater understanding of the injuries associated with traffic crashes (Watson et al., 2015). Data linkage is the process of linking sources of data (e.g., police reported crash data to hospital data) that belong to the same person. By using multiple linked data sources, researchers are able to identify, which individuals are most at risk on our roads. Further, the findings from studies which have used data linkage may assist with providing recommendations on where Government funding and resources should be allocated in order to target those at higher risk of road traffic crashes.

In terms of reducing road traffic crashes associated with human error, continued advancements in vehicle technology may also assist with improving safety. Examples of emerging technologies include intelligent speed assistance to manage speeds, lane departure warning systems, lane keeping assist, and automated emergency braking. Lane departure warning systems are designed to provide an auditory warning to the driver when the vehicle is close to the line marking. The driver is then expected to steer the vehicle away from the line marking. Lane keeping assist, however, is designed so that the vehicle will steer itself back within the line markings (without the need of human intervention). Automated emergency braking will first warn the driver if there is an object in front of the vehicle and the vehicle will then automatically brake if there is no response from the driver. As mentioned previously, the European Union is likely to mandate ISA starting 2022. As such, ISA will assist with improving the safety of vehicles in HICs and, in the longer term, might be a way to improve the safety of vehicle fleets in LMICs if these countries import secondhand vehicles from the European Union.

In summary, it is important that the research continues to assess why road users engage in risky driving behaviors and what can be done to reduce crashes associated with human error. The information gained from decades of trial and error of countermeasures in HICs has led to the development of best practice guidance and understanding of what needs to be done to reduce road crashes and the associated trauma burden. Appropriate legislation, enforcement and education, along with continued advancements in technology will assist with reducing fatalities and injuries in all countries. Importantly, the needs of LMICs might differ from the HIC context in a number of ways (e.g., cultural practices, mix and quality of vehicle fleet, quality of road infrastructure, availability of public transport, and existence of and accessibility to quality postcrash care). However, these differences do not mean that the same countermeasures will not work. Rather, it highlights the need for ongoing efforts to better understand how to continue to promote evidence-based countermeasures in all income contexts.

Introduction

Effective, safe evacuation is a critical component of transportation resilience. Resilience is the capacity to absorb shocks, to avoid disruptions, recover functionality and restore services quickly and efficiently. Transportation is an essential component of community resilience and transportation systems must also be resilient and resistant to shocks, interruptions, and disruptions (Kim et al., 2018b). Among the most important aspects of transportation is the safe, efficient movement of people away from harm. Evacuation planning involves anticipating threats and hazards and ensuring that vehicles, facilities, and services are available to move affected populations to safe locations. Perhaps the greatest “disaster” associated with Hurricane Katrina was the failure to safely evacuate thousands of residents when New Orleans was flooded.

In this article, the challenges and opportunities for evacuation planning are described. While evacuations are common, there are limited opportunities and resources available for practicing and preparing for the safe movements of people, pets, and their possessions out of harm’s way. The nature of the hazard or threat will affect the movements and behaviors of populations. There is need to understand decision-making processes as well as the physical systems and social systems for supporting both evacuation and sheltering of at-risk populations (Kim et al., 2018a). There are multiple hazards and threats, different travel modalities, many sources of information and channels for communications, and diverse populations who respond differently to warning and alerts. These factors and the potential for spontaneous actions, reactions, and behaviors complicate the planning and implementation of evacuation. Evacuation planners must be particularly sensitive to the physical, medical, social, and financial needs of evacuees. There is need for more research and better understanding of evacuation behavior and translation of this knowledge into effective plans, strategies, and training programs to build resilience. This article is structured around six aspects of evacuation planning: (1) evacuate or shelter-in-place; (2) evacuation travel modes; (3) origins and destinations for evacuees; (4) all clear and safe return; (5) technologies for detection, alert, and warning; (6) training and education.

Should I Stay or Go Now?

The choice as to whether or not to evacuate or remain in place is a function of information, risk tolerance, decision-making, and resources, including transportation assets. Evacuation involves first and foremost *mobility*, or the ability to move from one location to another, but also *accessibility*, or the use of transportation facilities, vehicles, and infrastructure to escape from harm. The evacuation decision involves the timing, source, credibility, and trustworthiness of information about a threat or hazard (Lindell and Perry, 2012). There must be sufficient time to receive, process, react, and respond to an evacuation order or to a perceived, impending threat. In the absence of official warnings and alert messages, there may be natural cues such as ground shaking, changes in atmospheric pressure or other signals that a potential hazard may strike. It is important to distinguish between short or no-notice events such as earthquakes, explosions, and sudden onset hazards and those such as distant tsunamis or approaching tropical cyclones or flooding for which there is time to prepare, mobilize, and evacuate. Other short notice hazards such as fires, industrial accidents, active shooters, or tornadoes may force evacuees to quickly evaluate threats, formulate escape plans, and move to safety. With some hazards, unfortunately, there is no time to react. A hazard can occur in the middle of the night, when most people are asleep and not aware of the danger. Other hazards such as building collapses or plane crashes can be unexpected events. There may also be rare or unusual events such as the Sarin gas attacks in the Tokyo subway system for which there is little knowledge and

experience with the hazard. For rare, unusual events, evacuees, and emergency managers may not be cognizant of the danger nor how best to respond, further delaying evacuation.

The trigger for the evacuation influences the evacuation order and the decision to evacuate. For weather and flooding events, there may be sufficient warning time so officials can issue an evacuation order. While a “mandatory” evacuation may be issued by a Mayor or emergency management official, people may or may not comply with the order. They may or may not believe that the danger is imminent. They may have experienced other evacuation orders for which harm did not materialize, sometimes referred to as the “cry wolf” effect. Other reasons for not evacuating include the fear of break-ins or burglaries or having pets and animals which need care and cannot not be easily transported. There are also households who may have mobility limitations or health conditions making it difficult to travel even under normal circumstances. Many people also serve as caregivers and either return or stay behind to assist others instead of evacuating.

While people may want to evacuate, they may lack the resources and ability to evacuate (Renne et al., 2011). They may learn of the threat too late or they may not have access to transportation modes to safely and successfully evacuate. They may have physical impairments or medical and mental conditions which prevent them from self-evacuating or taking early protective action. There may be language or communication barriers which affect reception of messages and limit knowledge of when, where, and how to travel. They may feel uncomfortable, unwelcome, or unable to travel because of their economic, social, or political status. Undocumented individuals, refugees, people of color, and those who fear law enforcement, border security and immigration officials may also be reluctant to evacuate, use public evacuation services, and shelters.

Walk, Bike, Drive, Carpool, Bus, or Ride Hailing Services

While the most common modality for evacuation involves the use of personal motorized vehicles, it is important to recognize that most people need to walk to get to their motor vehicles. Travel mode is also generally influenced by trip purpose (work, school, recreational, social, etc.) as well as other factors such as time of day, day of week, weather, and other factors. If evacuees are leaving from home or work or school, they may rely on their normal mode of travel. There has also been increased investment in bike infrastructure (bike lanes, shared bikes, other facilities) and increased awareness of health benefits associated with biking and walking which have promoted alternatives to driving, influencing mode choice both not only in terms of evacuation decision making, but also in terms of the exposure of travelers when evacuation orders are issued. It is important to realize that evacuations are also influenced by mode choice. In addition to trip purpose, the distance of the trip and the availability of fuel may also affect the modality.

Depending on both the hazard and the location, the vehicle may be used to transport other people, possessions, pets, and goods (food, water, clothing, survival supplies, etc.) needed during an evacuation. Households may use multiple vehicles and travel in groups to safety. They may coordinate evacuation plans, with rendezvous at key locations to gather people and goods, and to make collective decisions as to when to leave, where to go, and what or who to take or leave behind.

Unfortunately, there are also cases where individuals have been killed or hurt because they were trying to save their vehicles from harm, typically flooding, or because they were involved in motor vehicle collisions during the evacuation process. These effects can also hamper the movement and flow of traffic as well as create additional emergency response demands.

Carless households, low income populations, and those without extended social or familial support networks (Renne et al., 2011) may be more reliant upon public transport, taxi, paratransit or other shared ride services. Those who decide to evacuate early will have more options, resources, and destinations available to them, while those waiting until the last minute, will face greater competition from others trying to evacuate, as well as limitations imposed because of travel restrictions, closed facilities, and fewer drivers willing to travel into and out of hazard zones.

The role of public transit (Transportation Research Board, 2008) is complicated both with internal movements within an affected jurisdiction and especially if evacuees are transported outside of impacted cities, states, or countries. For a mass evacuation, there may need to be staging areas, pickup and temporary holding areas, transfer stations, and multimodal services (Kim et al., 2013) involving rescue vehicles, marine and air transport, and other vehicles and facilities pressed into service.

Friends and Family, Hotel, Campsite, or Public Shelter

Evacuation planning must also include identification of safe destinations. The most common, ideal location for most evacuees will be to travel to another family member’s or a friend’s home located outside of the hazard zone. This may entail traveling to another state or jurisdiction away from the threatened location. With a large event such as a hurricane, the homes of friends and family may also be impacted, requiring evacuees to travel further away and to seek shelter in a hotel or campsite or public shelter.

The challenge with destination planning is the multiplicity of stakeholders and the mix of public and private decision-making and use of resources. While many decisions and actions are made by individuals or households, not necessarily shared with public authorities, the impacts in terms of roadway traffic, congestion, and travel to safe locations impact public resources including law enforcement, transportation facilities, public works, utilities, availability of fuel, shelter, and other resources. Because schools, parks, and other facilities may be occupied by evacuees, normal operations and services may be impacted. A large number of evacuees from

another jurisdiction may strain physical, personnel, and fiscal resources for the receiving jurisdiction, creating disruptions, challenges, and conflict.

There may be other effects associated with a large mass evacuation including increased demand for hotel rooms, restaurant meals, as well as other goods and services associated with the movement of population to safe zones. It is useful to consider “plausible worst case scenarios” when doing evacuation planning (Kim et al., 2015). Some businesses may thrive while others in the impact zone may suffer losses due to cancellations or trip diversions and reduced spending. These impacts, dislocations, and secondary impacts suggest the need for receiving communities to also engage in evacuation planning.

One of the challenges to evacuation planning is the identification, tracking, and sharing of information regarding evacuees. Address information is useful to logistics planning and coordination of efficient transportation services. This may require the recording of names and other personal identifiers so that families can be reunited or evacuees can be transported via airlines or moved across borders and international boundaries. There are concerns with regard to privacy, identity theft, and exploitation of sensitive personal information. Evacuation planners must secure and protect confidential, sensitive, and private information about evacuees.

Evacuation planners should account for “who is left behind?” Some are left behind because they refuse to believe that the threat is real. Others are willing to accept the risk of harm, knowing that they are in a dangerous situation, but still choose to stay back. Others, such as those in institutions, prisons, and other facilities may not be free to travel and unless provisions have been made for evacuation, they may be left behind. There are caregivers and others providing important services or care for pets and livestock who may also need to stay back. There are others including those without transportation, economic resources, and ability to leave, who are left behind. Many of these people are also frail, require medical and social services, and have special needs. Others including homeless, undocumented people, minorities, nonEnglish speakers, and those who face oppression, discrimination, and stigmatization in society may also be left behind, in harms way.

All Clear, Return Home, and Back to Normalcy

For some hazards, such as man-made threats (active shooter, industrial accident, fire, etc.) the all clear or safe to return home message is a function of when the event has ended. For some weather events such as tornadoes or heavy rainfall, the duration and determination of the “all clear” is supported by detection and warning systems, satellite imagery, and other information systems. For hazards such as earthquakes, volcanoes, landslides, and complex disasters such as earthquake, tsunami, and nuclear disaster in Japan, the “all-clear” safe to return home message may not be so decisive or definitive. Moreover, even though the threat may have ended, there may be other hazards caused by a tornado or hurricane such as downed powerlines or environmental contamination that may create a lingering hazard, compelling authorities to limit access to evacuation zones. Heavily damaged structures can also be a risk to the health and safety of returning evacuees. Areas damaged by flooding or other natural hazards may also be impacted by wastewater spills or debris and require cleanup and restoration which may take time and delay the return to normalcy.

Evacuation due to social conflict may also create a lingering hazard or threat for which evacuees and those involved and the return home or resettlement may take a longer time period. Forced migration may begin with emergency evacuation, but lead to permanent relocation. In some locations with some disasters, the damage to homes and businesses is so extensive that people are forced to leave these communities permanently in search of new homes, jobs, and livelihoods. The “new normal” may mean that the community never returns to the level of population and economic activity that existed prior to the disaster and that evacuees never return home.

System restoration, therefore, is a function of the extent of damage and disruption caused by the harm-causing event. The greater the damaging forces and extent of destruction, the more widespread the evacuation and longer the duration of the evacuation. With small, localized events, households and businesses can return quickly, clean up and resume business as usual. With larger, complex, and devastating events, the return home and restoration of normalcy is delayed, protracted, or reinvented. Transportation plays a crucial role in not just evacuation but also reentry to the community (National Cooperative Highway Research Program, 2009).

For larger disasters, it may be necessary to restrict reentry to emergency repair workers, utilities, and to limit traffic to residents or those with passes or permits so that debris removal and repair of infrastructure can proceed ahead of other activities. Communities may want to impose these limitations to increase safety and security and limit outsiders, tourists, and others who may interfere with the recovery process.

The return home is a key metric for disaster resilience. How quickly, completely, and effectively residents and workers return following an evacuation is also a measure of the community’s resilience. Tracking and following evacuation behavior, therefore, provides evidence of a community’s detection, warning, and alert systems, but also the extent of preparedness and recovery capabilities. Having effective damage assessment, debris management, and restoration of services will hasten the return home and recovery from disasters.

New Technologies

Many new technologies affect evacuation behavior and evacuation planning. A useful framework for understanding the interactions between warning systems, evacuee decision making, and outcomes is the protective action decision model, which systematically considers diverse sources and channels for information, the credibility or “trustworthiness” of the information, how receivers and

evacuees process information and utilize it in decision making to formulate intended and actual actions and behaviors (Lindell and Perry, 2012) which result in outcomes (safe evacuation, sheltering from harm, or negative consequences such as death, injury, or other losses). The advent of social media, improved communications technologies, and widespread adoption of mobile computing and communications devices alongside diverse platforms and systems for disseminating, sharing, posting, hosting, and receiving information has both improved and complicated warning and detection processes. These technologies can also support the development of information systems for ensuring the safe, efficient movements of evacuees and their reunification with families and return home.

In the past, conventional media (radio, television, and print) were the primary sources of information about hazards and threats. While these sources still exist, there are many other ways in which people receive information about hazards and evacuation orders. The absence of a definitive source is also complicated by the fact that different federal, state, and local authorities are involved in the issuance of warnings and threat levels. While National Oceanic Atmospheric Administration (NOAA) is largely responsible for weather related events and while the United States Geological Survey (USGS) is responsible for earthquakes and volcanoes, there are shared responsibilities between national and regional and local centers. While tsunamis are most often triggered by earthquakes, the warnings are handled by NOAA. Flooding requires information about rainfall (NOAA) but also stream gauge data (USGS). While there have been improvements in sensors, satellites, and communications systems, there are ongoing challenges with the accuracy, timeliness, and extent of forecasts. While the prediction of storm tracks has improved, forecasts of wind speeds, storm surge, and localized damage needs additional development and testing. Advances in data integration and assimilation of information from multiple sources, ensemble forecasting, big data systems and application of machine learning and other advanced computational models support both early detection and effective response and recovery.

There is need for integration between scientific research and modeling and translation of hazards data into actionable information to support evacuation planning. In addition to the hazard and threat levels, it is important to have detailed information about the affected populations including not just their exposure to threats, but also their willingness and capabilities with respect to evacuation and sheltering. The integration of traffic monitoring systems with emergency management can help with the management of traffic during evacuations, but also provides vital information as to the location and movements of motorists in the hazard zones useful to understanding risk and exposure to disruption and the planning and design of mitigation strategies for reducing harm from natural and man-made hazards.

The improvement of tools for assessing and visualizing hazards such as (CAMEO, HAZUS, Sea Level Rise Viewer, COMMIT and other packages) needs to be accompanied with development of localized data sets and training of key personnel to integrate risk and vulnerability assessment and understanding of transportation evacuation models across highway, urban, and nonmotorized evacuation scenarios. It remains challenging to keep models, data, and personnel up-to-date with changes in local conditions and available technologies, system and software versions, and other updates.

In addition to hazard models, there are many evacuation models (Hardy et al., 2009; Murray-Tuite and Wolshon, 2013) with subroutines and packages built into or added onto systems such as TransCAD, TANSIMS, or CUBE, with different macro- (ETIS, HEADSUP, PC DYNEV), micro- (CORSIM, VISSIM, DYANMIT, Paramics) and meso-scale (DYNASMART-P), Integration 2.0, EMME/2, OREMS) models with varying input requirements that typically include not just origins and destinations but also vehicle occupancies, loading factors, roadway capacities, and directionality resulting in outputs such as travel times, speed, delay, volume, congestion, capacity utilization and emergency management outcomes such as clearance times, and cumulative proportions of those evacuees who have left the danger zone. Greater dissemination of tools and datasets, model results, and examples of how these advances have been used in evacuation plans along with evaluation of actual evacuation plans, orders, and cases would be helpful to the development of training and education.

Training and Education

The key to improved evacuation planning is training and education. There is a need for more evacuation simulations, exercises and drills, and evaluation of these efforts. Such efforts are costly and require financial resources, personnel commitments, and specialized knowledge, skills, and equipment for modeling, mapping, and making effective evacuation plans. A commitment to training and education requires strong leadership and the involvement of not just management, but also operations and field staff within and across agencies responsible for transportation, law enforcement, public facilities, and health and human services. Training and education should be coordinated not just across federal, state, and local agencies, but also with private and nongovernmental organizations involved in evacuation and sheltering. More attention to special needs populations is especially needed.

While a core element of evacuation planning involves the training and education of engineers, it is also important to include others involved in the planning, management, and operation of the facilities, vehicles, and services associated with evacuation (Matherly et al., 2013). Often those involved with large-scale special events such as hosting a Superbowl or Olympics or major convention or international gathering, have experience in multi-modal planning, managing crowds, accommodating special needs, or unusually high levels of demand for transport and other services. Those familiar with travel demand modeling with an understanding of origins and destinations, mode choice, and network constraints have a foundation for the development of evacuation plans. Moreover, those who run transit systems, paratransit operations, manage parking facilities, ferries, airports, and commuter facilities also understand the movements, capacities, and flows of critical components of transportation supply and demand. While there is need to adjust time frames and to account for complexities caused by changing conditions and the

reactions of travelers, those already in the transportation industry have the knowledge, skills, and professionalism to support successful evacuation.

The National Disaster Preparedness Training Center funded by the US Department of Homeland Security and the Federal Emergency Management Agency has developed evacuation training for state and local governments. In addition to reviewing case studies on evacuation, the course delves into the key operational strategies for making use of real-time traffic data, signage, pavement markings, barricades, coordination of traffic controls, roadway configurations, contraflow, intersection management, and other adaptive strategies for managing roadway, transit, and other assets for improving emergency evacuation. In addition to highway operations, there is also need to coordinate bus and paratransit operations and manage other transportation assets (school buses, shuttle, rail, and commuter services). Other demand management strategies include school closings, timed/staged government employee release, and encouragement of shelter-in-place strategies where appropriate. The course includes modules on estimation of the evacuee population to include not just residents and employees, but also tourists, transient populations, institutionalized populations, and other at-risk groups. Needs of diverse travelers may vary widely. Key sources of information include paratransit operators, faith-based organizations, social service providers, and the visitor industry. The course recommends dividing evacuees into three groups: (1) vehicle based, self-evacuees; (2) assisted self-evacuees (transit, taxi, rideshare, etc.); and (3) assisted evacuees (medical, paratransit, institutionalized, schools, etc.). A key element of the course involves lessons from Katrina, Ivan, Rita and other large storms with regard to messaging, information sharing, coordination between emergency management, transportation agencies, law enforcement and other key stakeholders. Other training courses have been developed in Australia (focused on wildfires) and in other countries for specific hazards such as tsunamis and volcanoes in Indonesia.

Among the most developed evacuation plans are those required by the US Nuclear Regulatory Commission in communities with nuclear power plants. These plans need to be updated periodically or when the affected population or travel conditions change significantly and include evacuation planning for schools, special facilities, and vulnerable populations. In addition to detailed evacuation time estimates, the modeling procedures also require estimates of “shadow evacuations” for those who do not need to evacuate but do so anyway, adding to network traffic, and the effects of warnings on the behavior of vulnerable populations. There are valuable lessons to be learned by examination of not just communities that have conducted recent evacuations, but also from those communities which have developed and practiced evacuation plans. There is value to studying “after action” reports lessons learned, and evaluations of exercises, tabletops, and drills carried out by state and local governments. More systematic evaluation and sharing of knowledge is needed.

Resilient Evacuation Planning

Resilient evacuation planning begins with understanding of needs, capabilities, decision making, and the social context in which evacuees receive, process, and act to take protective actions. At the core of decision making is understanding of risk, that is the likelihood of events, and the consequences of those events. There is both the *actual risk* or threat created by a particular hazard and *perceived risks* based on the information, experience, and influences from media, friends, and family, and others with whom the evacuee is connected. Evacuees may choose to ignore or accept crucial information. They may decide to delay decision making. They may follow or heed the advice of others who may or may not have full information nor possess robust decision-making capabilities. These factors and influences complicate the issuance of warnings and alerts, evacuation orders, and the efforts of emergency managers and those involved in executing evacuation plans.

As described in this article, the transportation system is comprised of many different moving parts. There are different modalities, technologies, vehicles, facilities and networks for movement and communications which influence understanding of how, when, where, and with whom evacuation occurs. There are also different hazards and threats with varying degrees of impact, physical forces, duration, extent, and disruption. Many of these hazards can also cripple transportation assets, impacting the evacuation efforts. There are also many different agencies, organizations, and assets which need to be deployed at the management and operational levels to ensure safe, efficient evacuation. Greater emphasis on the physical, medical, social, and economic needs of evacuees must be included in evacuation plans. Investments in training and the development of operational procedures supports not just knowing what to do and how to accomplish it, but also the formation of relationships and trust between emergency managers, transport operators, law enforcement, social service providers, and others who need to work collaboratively in evacuation planning.

With longer term threats, such as climate change and sea level rise and increased frequency and intensity of storms, flooding, wildfires, and other natural hazards, there are opportunities now to invest in the design, planning, engineering, financing, and construction of mitigation strategies to either lessen the need for evacuation or support positive outcomes if evacuation orders are implemented. These investments include more sensors and equipment for detecting hazards, improved communications and warning systems so that vulnerable populations receive earlier evacuation orders, and improving the sheltering-in-place and increasing neighborhood refuges and safe zones which are easily accessible to evacuees. Tsunami evacuation buildings, elevated safe havens from flooding, and structures designed to withstand various hazards need to be designed, built, and designated within hazard prone communities. By engaging communities in the planning and design of local evacuation strategies, coupled with mitigation and adaptation projects and effective training programs planners and engineers can increase awareness, capabilities, and resilience among those most at risk of harm. Communities must fully engage in equal opportunity evacuation planning so that *no one is left behind*.

Biography

Karl Kim is Professor of Urban and Regional Planning at the University of Hawaii at Manoa, and Director of the graduate program in Disaster Management and Humanitarian Assistance. He studies transportation, cities, and resilience. He served as the Chief Academic Officer (Vice Chancellor for Academic Affairs) overseeing tenure and promotion, strategic planning, international programs, and program review for the University of Hawaii. He is Executive Director of the National Disaster Preparedness Training Center (ndptc.hawaii.edu), authorized by the US Congress to develop and deliver FEMA certified training courses for underserved, at-risk communities on natural hazards, mitigation, and urban planning. The Center has trained more than 50,000 first responders, emergency managers, and leaders in over 400 different communities across the world. Dr Kim has served as the Chairman of the National Domestic Preparedness Consortium (ndpc.us). He has published many papers on disaster management, transportation, and urban planning. He is Editor-in-Chief of *Transportation Research Interdisciplinary Perspectives* (Elsevier) and is editor of a 10-volume series on disaster risk reduction and resilience (Routledge). He has been a Fulbright Scholar to Korea and the Russian Far East. Dr Kim was educated at Brown University and the Massachusetts Institute of Technology.

Introduction

Exposure is a critical factor in risk analysis and one of the primary predictors of crashes and other harmful events. Want to avoid a shark bite? Stay out of the ocean. Similarly, if you want to avoid a car crash, stay off the road. Obviously, if there were no motor vehicles on the road, then there would be no motor vehicle crashes. Since the chance of eliminating vehicles on the roadway is about the same as keeping swimmers out of the ocean, there is a need to understand how to account for exposure in estimating crash risk.

There are numerous measures of vehicle exposure such as traffic volume, segment length, and vehicle-kilometers traveled (VKT). There are also various measures of nonmotorized exposure such as pedestrian volumes, bicycle volumes, and time or distance traveled on a given facility type. The appropriate measure of exposure depends on the question at hand and the subject of interest. The following sections present different measures of exposure used to account for differences in crash risk and the applicable questions that could be answered related to traffic safety.

Per Capita

A very basic measure of exposure is the population of a given geographic area. Per capita means per population, which might be expressed per thousand or per million people. Per capita is a good measure of exposure when assessing risk in terms of overall public health. If the focus is on reducing the number of people injured or killed in motor vehicle crashes, then this is the measure to use. Per capita is not a reliable measure to predict the safety performance of a specific location because it does not account for the many factors that contribute to changes in risk such as the number of road users, type of road users, type of facilities, and distance traveled by mode and facility type.

The following are potential questions answered using the population as the measure of exposure:

- What is the difference in crash risk by population group?
- What is the difference in crash risk by geographic area?

Licensed Drivers

Another basic measure of exposure is the number of licensed drivers. This is similar to the population-based measure of exposure (per capita) but limits the population to those with a driver license. Similar to per capita, the number of licensed drivers is not a reliable measure to predict the safety performance of individual locations because it also does not account for the many factors that contribute to changes in risk such as the number of road users, type of road users, type of facilities, and distance traveled by mode and facility type. It is also not the most reliable measure of exposure when looking at this from a public health perspective. For example, the number of licensed drivers does nothing to account for the number of school-aged children who walk to school or the types of roadways the licensed drivers travel.

Registered Vehicles

Another spin on population-based measures of exposure is the vehicle population. Specifically, the number of registered vehicles is a common measure of exposure for computing and comparing crash rates over time. Similar to the number of licensed drivers, the number of registered vehicles is not a reliable measure of crash risk because it does not account for the distance traveled or the types of facilities traveled by those vehicles. For example, a car collector may have a 1956 Ford Thunderbird in their collection and drive it not more than 100 km per year, most of which are on a closed course as part of a car show; however, this vehicle would count toward the number of registered vehicles. Further, there are more registered vehicles in the United States than there are licensed drivers (225 million licensed drivers and 273 million registered vehicles in 2017; [USDOT, 2018](#)) and it is not possible to drive two vehicles at the same time.

Vehicle-Kilometers Traveled

VKT [or vehicle-miles traveled (VMT)] is applicable to crash risk related to motor vehicles. This measure of exposure accounts for the number of vehicles on the roadway and the distance traveled by those vehicles.

In the United States, data for this measure come from the Federal Highway Administration (FHWA) Highway Statistics ([USDOT, 2019](#)). The reports are based on individual state reports on traffic data counts collected through permanent automatic traffic recorders on public roadways. Data for urbanized areas are available from the FHWA Highway Statistics Series ([USDOT, 2018](#)). Some countries collect this type of data in slightly different ways. In Sweden, there are estimates of VKT, but most official data are vehicle-axle-pairs because the average axle-numbers per vehicle are not known well enough for site-level analysis.

We have already established that crash risk increases as traffic volume increases. But this is a general relationship and the change in crash risk differs for different types of vehicles, types of roads, and groups of drivers. VKT could be stratified in a number of ways such as by vehicle type (e.g., passenger cars vs. large trucks), facility type (e.g., urban vs. rural), or driver type (e.g., younger vs. older drivers) to compare crash risk.

The following are potential questions answered using VKT as the measure of exposure:

- What is the difference in crash risk by vehicle type?
- What is the difference in crash risk by facility type?
- What is the difference in crash risk by driver age?

When comparing crash risk among vehicle types, it is important to account for the number of kilometers traveled by those vehicles. For example, there are many more crashes involving passenger cars than large trucks; however, the VKT for passenger cars is also much greater than the VKT for large trucks. In 2016 in the United States, there were approximately 21,000 passenger cars (excluding motorcycles and light trucks) involved in fatal crashes and approximately 4200 large trucks involved in fatal crashes. While the number of passenger vehicles involved in fatal crashes is approximately 5 times greater than the number of large trucks involved in fatal crashes, the involvement rate of passenger cars, using VMT as the measure of exposure, is nearly identical (1.45 passenger cars involved in fatal crashes per 100 million VMT compared to 1.46 large trucks involved in fatal crashes per 100 million VMT).

Similarly, when comparing crash risk among facility types, the number of kilometers by facility type is not likely to change dramatically from one year to the next; however, crashes, injuries, and fatalities change from year to year and there is a need to understand how much of this is due to changes in exposure. In 2016 in the United States, there were 4445 fatal crashes on interstates and 4022 fatal crashes on local roads. While the number of fatal crashes is slightly higher on interstates, the fatal crash rate, using VMT as the measure of exposure, is much higher on local roads (0.55 fatal crashes per 100 million VMT on interstates compared to 0.93 fatal crashes per 100 million VMT on local roads).

When comparing VKT from year to year, it is also important to understand if there are changes in VKT by age group. For example, younger (less experienced) drivers tend to have a higher crash risk compared to older (more experienced) drivers. Therefore, it is conceivable that the overall crash risk for the system could decrease even if VKT increased or remained the same from one year to the next. This might be the case if VKT decreased for younger drivers and increased for more experienced drivers. To capture the relationship between crash risk and exposure, this scenario would require information by age group. Specifically, there would be a need to know the VKT by age group and the number of crashes by age group. With this information, one could model the relationship and predict the overall change in crash risk given a predicted change in travel by age group.

Nonmotorized Road Users

Nonmotorized users may include any person on foot, walking, running, jogging, hiking, sitting, lying down, or any person on personal conveyances such as bicycles, roller skates, inline skates, skateboards, baby strollers, scooters, Segway-style devices, wheelchairs, and scooters for those with disabilities. The crash risk for these users depends on factors such as the number of users by mode and distance traveled by user group and facility type. The exposure could also differentiate the distance traveled along

roadway and distance traveled when crossing the roadway. These numbers are much more difficult to track than motor vehicles because in the United States the typical traffic counters that track the number of vehicles on the road do not collect numbers for nonmotorized travel, and we also do not register these vehicle types as we do with motor vehicles. In some countries, bicycle and pedestrian flows are collected on a large number of facilities but in the United States they are typically counted only at a few intersections in central parts of cities, and those counts are done manually by hand. Agencies are starting to use newer video analysis and mobile applications for smartphones are beginning to track some information about pedestrian and bicycle exposure. Also, household surveys in some countries capture estimates of walking and biking distances; however, this is only for a sample of the country's population, only for one day of the year, and most countries do not execute the surveys every year. More research is needed to obtain accurate estimates. Once these estimates are available, it will be useful to generate and compare crash rates by various demographics (age and gender), locations (intersection and midblock), area types (urban and rural), and other categories. It will also be useful to model the statistical relationship between crash risk and exposure. For example, the United Kingdom and Sweden have developed models to estimate the number of crashes based on the number of vehicles crossing the crosswalk and pedestrian daily flow. A hypothetical example of this relationship is shown in Eq. (1).

$$\text{Pedestrian crashes} = \text{vehicles crossing crosswalk}^{0.5} \times \text{pedestrian daily flow}^{0.5} \quad (1)$$

Annual Average Daily Traffic (AADT)

The previous measures of exposure help to compare crash risk among general groups (e.g., populations, regions, and facility types), but how would you measure the crash risk for a single site (e.g., intersection or roadway segment)? Research has shown that traffic volume is one of the single most important predictors of crash risk for a given location (AASHTO, 2010; Hauer, 1994). Again, no traffic, no crashes. For roadway segments such as tangents, curves, and ramps, the annual average daily traffic (AADT) and segment length are common measures of exposure. Crash risk increases as traffic volume and segment length increase. The AADT is typically the two-way traffic volume, but could include directional, hourly, or sub-hourly traffic volume. For intersections, the AADT on the major and minor road, or total entering vehicles, are common measures of exposure. When using the total entering volume, the crash risk is typically expressed as crashes per million entering vehicles; however, the crash risk may change for different proportions of traffic on the major and minor road even when the total entering vehicles is the same. As such, it is often more reliable to account for differences in AADT on the major and minor road.

Using Exposure Responsibly

It is important to account for exposure, but it is just as important to do so responsibly. Traditionally, analysts have used crash rates to account for differences in exposure among sites. Crash rate is the ratio of crash frequency to exposure as shown in Eq. (2), where the crash frequency of interest could be the count of crashes by type or severity, and the measure of exposure could be population, registered vehicles, VKT, nonmotorized users, or AADT as described above.

$$\text{Crash rate} = \frac{\text{Crash frequency}}{\text{Measure of exposure}} \quad (2)$$

Crash rates implicitly assume a linear relationship between crash frequency and the measure of exposure; however, many studies have shown that the relationship between crashes and traffic volume is often nonlinear, and this relationship depends on the facility and site type (Hauer, 1997). While crash rates may be useful for high-level comparisons of crash risk among populations, vehicle types, and facility types, crash rates are not a reliable measure to rank sites for potential investment. The remainder of this section explains the limitations of using crash rate to compare the safety performance among sites as illustrated through an example.

Table 1 provides data for three hypothetical sites that an agency is considering for further study and potential investment to improve safety. Site 1 has an average of six crashes per year with an AADT of 2000 vehicles per day and corresponding crash rate of 0.0030 (crashes per AADT). Site 2 has an average of eight crashes per year with an AADT of 5000 vehicles per day and corresponding crash rate of 0.0016 (crashes per AADT). Site 3 has an average of 11 crashes per year with an AADT of 10,000 vehicles per day and corresponding crash rate of 0.0011 (crashes per AADT).

Table 1 Ranking of hypothetical sites by crash frequency and crash rate

Sites	Crash frequency	Traffic volume (exposure)	Crash rate (crashes/exposure)	Rank by frequency	Rank by rate
1	6	2000	0.0030	3	1
2	8	5000	0.0016	2	2
3	11	10,000	0.0011	1	3

Figure 1 Hypothetical SPF relating crash frequency and traffic volume.

Figure 2 Example of site selection using exposure in different ways.

Consider the three hypothetical sites from [Table 1](#) and two performance measures to rank the sites for further investigation: crash frequency and crash rate. Using crash frequency, the sites are ranked 3, 2, and 1 where site 3 is the highest priority as shown in [Table 1](#). Using crash rate, the sites are ranked 1, 2, and 3 where site 1 is the highest priority as shown in [Table 1](#). Clearly, one can make an argument to account for exposure when comparing safety performance because one would expect more crashes at sites with higher traffic volumes than sites with lower traffic volumes. If the analyst does not account for differences in traffic volume among sites, then they may incorrectly identify sites with higher traffic volumes as sites with higher potential for safety improvement. On the contrary, a site with a single crash and relatively low exposure would have a relatively high, and potentially misleading, crash rate.

The safety literature has shown that nonlinear relationships are more appropriate than linear relationships such as crash rates to account for differences in traffic volume among sites when comparing safety performance. Specifically, safety performance functions (SPFs) are a more reliable method to account for differences in traffic volume among sites because they reflect the nonlinear relationship between crash frequency and traffic volume. The SPF is an equation, representing a best-fit model that relates annual observed crashes to the annual traffic volume for a group of sites with similar attributes. [Fig. 1](#) is a hypothetical SPF where the points represent observed crashes at specific traffic volumes for individual sites, and the solid line represents the best-fit model (i.e., the SPF). Given an SPF and the traffic volume (i.e., exposure) for a specific location, one could predict the crashes for that location. For example, at an AADT of 5000 vehicles per day, this SPF predicts approximately nine crashes.

Now, let's revisit the data from [Table 1](#) and include a linear threshold (average crash rate) and nonlinear threshold (i.e., SPF) in the mix. [Fig. 2](#) plots the hypothetical data from [Table 1](#) and illustrates the difference between a linear and nonlinear relationship between crash frequency and traffic volume. In [Fig. 2](#), the dashed line is the average crash rate for similar sites, representing a linear relationship between crash frequency and traffic volume. The solid line is the SPF for similar sites, representing a nonlinear relationship between crash frequency and traffic volume. As performance measures, these lines provide a threshold representing the average crashes for a given traffic volume. Sites above the line represent sites with the greatest potential for safety improvement and sites below the line represent sites performing relatively well with respect to other similar sites with similar traffic volumes. Note that sites below the line may still present opportunities for safety improvement.

Using the average crash rate as the threshold, assuming a linear relationship, the sites are ranked 1, 2, and 3. It is apparent that sites 1 and 2 have potential for improvement because the actual crash frequency is greater than the predicted crash frequency for that level of exposure. Site 1 is the highest priority because it shows the greatest potential for improvement. Using the SPF as the threshold,

Table 2 Before–after analysis of hypothetical curve improvement project

Performance measure	Before treatment	After treatment	Safety improvement?
Average crash frequency (crashes/year)	3.5	4.2	No
Average traffic volume treatment (vehicles/day)	3000	4000	
Crash rate (crashes/million-vehicles)	3.2	2.9	Yes

**Figure 3** Hypothetical SPF for predicting crashes on curves.

assuming a nonlinear relationship, the sites are again ranked 1, 2, and 3 where site 1 remains the highest priority; however, site 1 is the only site that shows a clear need for improvement. For sites 2 and 3, the actual crash frequency is lower than the predicted average crash frequency, indicating these sites are performing relatively well compared to similar sites with similar exposure.

If the actual relationship between crashes and traffic volume is nonlinear, and the analyst assumed a linear trend as the threshold to represent the average crashes for a given traffic volume, then they would incorrectly identify any sites between the SPF and dashed line (site 2 in this case) as priority sites for further investigation. It is important to understand that different performance measures can produce different priority rankings and the more reliable performance measures (i.e., those based on SPFs) can lead to the identification of sites with greater opportunity for safety improvement and better investment of safety improvement funds. When it is not possible to use SPF-based performance measures to identify sites with potential for safety improvement, then crash frequency can serve as a reasonable alternative (Srinivasan et al., 2016b). If crash rate is used to identify sites with potential for safety improvement, then it is important to incorporate the average crash rate as a threshold and use performance measures such as critical crash rate.

As another illustration of the potential differences in results from different performance measures, consider a before–after safety evaluation (Srinivasan et al., 2016a). Agencies regularly conduct before–after evaluations to estimate the safety impacts of completed projects. For example, let's assume an agency installed advance curve warning signs and chevrons to address curve-related crashes. Three years after implementation, the agency evaluates the effectiveness of the chevrons to determine if the treatment improved safety. Table 2 presents information gathered for the analysis. Using crash frequency as the performance measure, the agency would conclude there was no safety improvement because the number of crashes increased from 3.5 per year to 4.2 per year. Using crash rate as the performance measure, the agency would conclude there was a safety improvement because the crash rate decreased from 3.2 per million-vehicles to 2.9 per million-vehicles. Now, let's assume the agency had access to the SPF in Fig. 3 that represents similar curves, allowing them to predict crashes based on traffic volume. Plotting the actual crash frequency before and after on the same scale as the SPF, it is apparent that the actual crashes before and after treatment are similar to the predicted crashes based on the traffic volumes before and after. In this case, the agency would conclude the treatment did not impact safety performance (i.e., no change relative to other similar sites with similar traffic volumes). Given this information, the agency might decide to try something different at this location to improve safety.

Current Practice for Estimating Crash Risk

The current state of the practice for estimating crash risk is to use negative binomial regression models to explain the relationship between number of crashes and exposure. This is reflected in the predictive methods in the Highway Safety Manual and related research (AASHTO, 2010). For segments, exposure includes segment length and AADT. For intersections, exposure includes traffic volumes on the major and minor roads or total entering vehicles. The following equations form the basis of SPFs. Agencies use these functional forms with data from their jurisdiction to estimate the coefficients through regression modeling. While it is possible to calibrate existing SPFs from another agency, it is typically more reliable to develop agency-specific SPFs.

Eq. (3) shows the functional form for a typical crash prediction model for roadway segments. The predicted crashes ($N_{\text{predicted}}$) are estimated based on segment length (L) and AADT. Eq. (4) is the same equation transformed using the natural log function. This transformation allows for the estimation of the coefficients (a and b) using linear regression. In these equations, " a " is the intercept and " b " is the regression coefficient for AADT.

$$N_{\text{predicted}} = L \times e^a \times \text{AADT}^b \quad (3)$$

$$\ln(N_{\text{predicted}}) = \ln(L) + a + b \times \ln(\text{AADT}) \quad (4)$$

Eqs. (5) and (6) show a slight variation of the functional form and transformed equation for a crash prediction model for roadway segments. In Eqs. (3) and (4), segment length is treated as an offset where the predicted number of crashes is linearly related to the length of the segment. A coefficient " c " is added to Eqs. (5) and (6) to allow for a nonlinear relationship between the predicted crashes and segment length.

$$N_{\text{predicted}} = L^c \times e^a \times \text{AADT}^b \quad (5)$$

$$\ln(N_{\text{predicted}}) = c \times \ln(L) + a + b \times \ln(\text{AADT}) \quad (6)$$

Eqs. (7) and (8) show the typical functional form and transformed equation for a crash prediction model for intersections. The predicted crashes ($N_{\text{predicted}}$) are estimated based on the major road AADT (AADT_Major) and the minor road AADT (AADT_Minor).

$$N_{\text{predicted}} = e^a \times \text{AADT_Major}^b \times \text{AADT_Minor}^c \quad (7)$$

$$\ln(N_{\text{predicted}}) = a + b \times \ln(\text{AADT_Major}) + c \times \ln(\text{AADT_Minor}) \quad (8)$$

Finally, Eqs. (9) and (10) show a slight variation of Eqs. (7) and (8) where the predicted crashes ($N_{\text{predicted}}$) are estimated based on the total entering traffic volume (AADT_Total) rather than separating the AADT on the major and minor road.

$$N_{\text{predicted}} = e^a \times \text{AADT_Total}^b \quad (9)$$

$$\ln(N_{\text{predicted}}) = a + b \times \ln(\text{AADT_Total}) \quad (10)$$

The following is an illustrative example of why it may be preferable to account for both the major and minor road AADT in the model (i.e., the proportion of traffic on the major and minor road can change the estimated safety performance depending on the facility type). Consider two rural, four-legged intersections with similar geometry and the same total entering volume, say 10,000 vehicles per day. The difference is the split in traffic on the major and minor road. Intersection 1 has 9000 vehicles per day on the major road and 1000 vehicles per day on the minor road. Intersection 2 has 5000 vehicles per day on the major road and 5000 vehicles per day on the minor road. Eq. (11) represents the SPF for a rural, four-legged, two-way stop-controlled intersection from the United States Highway Safety Manual. Eq. (12) represents the SPF for a rural, four-legged signalized intersection from the United States Highway Safety Manual.

$$N_{\text{predicted}} = \exp(-8.56 + 0.60 \times \ln(\text{AADT_Major}) + 0.61 \times \ln(\text{AADT_Minor})) \quad (11)$$

$$N_{\text{predicted}} = \exp(-5.13 + 0.60 \times \ln(\text{AADT_Major}) + 0.20 \times \ln(\text{AADT_Minor})) \quad (12)$$

Table 3 shows the predicted crashes for each of the scenarios after plugging in the values for major and minor road traffic volume. With two-way stop-controlled intersection, the predicted crashes for Intersection 1 are 2.40 crashes per year and the predicted crashes for Intersection 2 are 3.72 crashes per year. It is apparent that the proportion of traffic on the major and minor road impacts the safety performance of an intersection, and, in this case, Intersection 1 is predicted to perform better than Intersection 2 with respect to safety. With signal control, the predicted crashes for Intersection 1 are 4.35 crashes per year and the predicted crashes for Intersection 2 are 4.05 crashes per year. Again, the proportion of traffic on the major and minor road impacts the safety performance of an intersection; however, in this case, Intersection 2 is predicted to perform slightly better than Intersection 1 with respect to safety.

Table 3 Predicted crashes for intersections with different proportions of major and minor volumes

Intersections	Major road volume	Minor road volume	Predicted crashes with two-way stop-control	Predicted crashes with traffic signal
Intersection 1	9000	1000	2.40	4.35
Intersection 2	5000	5000	3.72	4.05

Future of Estimating Crash Risk

The current state of the practice for estimating crash risk is based on annual measures of exposure (e.g., population, VKT, and AADT). As technology advancements allow for the collection and analysis of more disaggregate exposure data, the state of the practice will likely move toward the estimation of risk at a more disaggregate level. However, this will depend on the availability of data and the question at hand. For example, if the question at hand is related to the risk of different populations, and the resulting answer would guide decisions related to education programs that would not change more than once per year, then it would not be necessary to use disaggregate data such as sub-hourly volumes by population to estimate crash risk. However, if the question was related to the real-time risk of a roadway segment or intersection, and the answer would guide decisions related to the real-time operation of the site, then sub-hourly or real-time exposure data would be quite useful. For example, consider a freeway corridor with ramp metering in place. If an agency has access to real-time exposure data (e.g., traffic volumes on the freeway and on-ramp), then they could monitor the change in risk and activate the ramp metering when the risk exceeded a certain threshold.

End Note

When calculating and comparing crash risk, it is important to account for exposure and to do so properly. Traditional methods account for exposure through linear crash rates (simply dividing the number of crashes by the exposure). More reliable methods establish a threshold and allow for the typical nonlinear relationship between crashes and exposure. It is also important to use an appropriate measure of exposure and to consider the data required to answer the question at hand. As such, it is useful to stop and ask yourself questions such as:

- What measure of exposure should be used for the risk analysis/assessment?
- What level of detail is required in the exposure data to answer the question at hand (e.g., annual, daily, hourly, sub-hourly volumes, etc.)?

Biography

Dr. Frank Gross, PE, is a principal at VHB with over 15 years of diverse transportation research and engineering experience. As a researcher, he specializes in the development of national guidance and tools to support data-driven decision-making, including research to support the Highway Safety Manual. As a highway safety engineer, he implements and promotes the use of these national tools, supporting state and local agencies with their programs, focusing most recently on the Highway Safety Improvement Program. His national exposure keeps him informed of the latest tools and techniques. His experience at the state and local level keeps him informed of the common challenges and opportunities to overcome challenges in transportation management efforts.

Highway Statistics Series.

The Highway Statistics Series consists of annual reports containing analyzed statistical information on motor fuel, motor vehicle registrations, driver licenses, highway user taxation, highway mileage, travel, and highway finance.

Available from: <https://www.fhwa.dot.gov/policyinformation/statistics.cfm>.

Traffic Safety Facts.

Traffic Safety Facts presents descriptive crash statistics to help understand national and statewide trends. The crash statistics included in Traffic Safety Facts are generated from two data systems: (1) the Fatality Analysis Reporting System (FARS) and (2) the General Estimates System (GES). FARS contains data on traffic crashes in which someone was killed. GES contains data from a nationally representative sample of police-reported crashes of all severities, including those that result in death, injury, or property damage.

Available from: <https://cdan.nhtsa.gov/tsftables/tsfar.htm>.

Travel Monitoring: Traffic Volume Trends.

Traffic Volume Trends is a monthly report based on hourly traffic count data reported by the States. These data are collected at approximately 5000 continuous traffic counting locations nationwide and are used to estimate the percent change in traffic for the current month compared with the same month in the previous year. Estimates are readjusted annually to match

the vehicle kilometers of travel from the Highway Performance Monitoring System and are continually updated with additional data.

Introduction

In this article, types, safety, and security of ferry vessels and cruise ships are discussed.

Ferry Vessels

A ferry vessel is a passenger vessel used to transport passengers and sometimes vehicles (e.g., automobiles of ferry passengers) and cargoes of shippers from ferry marine terminals as origin to ferry marine terminals as destination (<https://en.wikipedia.org/wiki/Ferry>). Shipper cargoes are stored aboard ferry vessels: (1) individually, (2) in packages and containers, and (3) in the land freight transportation vehicles used in the transportation of the cargoes from pick-up sites to ferry marine terminals. Ferry vessels that transport vehicles are described as roll-on/roll-off ferries. The transportation of passengers by ferry vessels in urban areas, where the vessels follow fixed-water routes and fixed-time schedules in the areas, is a type of urban transit passenger transportation service (Talley, 1983). This type of ferry vessel has the distinction in being larger in size than urban transit passenger land vehicles by having the capacity to transport up to 2500 passengers per trip (Talley, 1983, p. 293).

Types of Ferry Vessels

The types of ferry vessels used in the provision of transportation services will depend upon the (1) physical characteristics of the water routes over which ferry-vessel transportation services are provided (e.g., lengths in miles and the extent to which water currents and waves exist), (2) weather conditions of the water routes (e.g., the extent of rain and snow precipitations and cold versus warm temperatures on the routes), and (3) whether vehicles and cargoes are transported by ferry vessels.

Hovercraft ferry vessels in the 1960s and 1970s were built to transport passengers and their automobiles. The SR.N4, the largest hovercraft vessel built, allows automobiles to enter its central section via ramps at both its bow and stern and was used to transport automobiles between England and France. The hovercraft is supported by a cushion of air with boundaries defined by a rubber skirt in which it sits (Wang and Mcowan, 2000). Its lift is provided by a fan system that blows air into the cushion and its propulsion is provided by engines.

Hydrofoil ferry vessels have the advantage of relatively high cruising speeds. The two main types are the fully submerged hydrofoil vessel and the surface piercing hydrofoil vessel. Hydrofoil ferry vessels replaced hovercraft ferry vessels on English Channel routes that competed with the Eurotunnel and Eurostar passenger trains using the English Channel tunnel.

Catamaran ferry vessels revolutionized ferry vessel services. A catamaran ferry vessel is a twin-hull vessel with slender hulls (or pontoons), having the advantage of stability and being less susceptible to adverse sea conditions versus hydrofoil ferry vessels. Since 1990, hovercraft and hydrofoil ferry vessel services have been replaced with Catamaran ferry vessel services. The Stena HSS class catamaran (once the largest catamaran vessel in the world) is waterjet powered and is operated by Stena Line between the United Kingdom and Ireland, accommodating 1500 passengers and 375 passenger cars. High-speed (exceeding 30 knots) ferries are technically known as high-speed crafts (HSCs). The catamaran is the most commonly used HSC by passenger ferry operators as opposed to using, for example, the hydrofoil HSC ferry (Wang and Mcowan, 2000).

Other types of ferry vessels include the (1) *monohull* ferry that has greater cargo-carrying capacity than the catamaran; (2) small waterplane area twin hull (SWATH) ferry that has a bulbous shape that allows it to rise in the water as the speed of the vessel increases, providing a dynamic lift; (3) surface effect ship (SES) ferry that combines aspects of the catamaran and the hovercraft to produce a vessel with the advantages of both vessels and the disadvantages of neither; (4) *double-ended* ferry that has interchangeable bows and sterns that allow it to shuttle back and forth between marine terminals without having to turn around; (5) *train* ferry that is fitted with railway tracks and front and/or rear doors that provide access to wharves for the transportation of rail cars; (6) *foot* ferry is a small ferry that is used to transport foot passengers and cyclists across small waterways (such as rivers); and (7) *RoPax* fast ferry that has relatively large garage intake and passenger capacities, with conventional diesel propulsion, generating vessel speeds exceeding 25 knots and in 1995, these were used to provide fast ferry service between Greece and Italy. High-speed ferries (hovercrafts and catamarans) can operate at speeds exceeding 30 knots. Ferry carriers that operate large ferries around the world include: Sealink (operating between the United Kingdom, Ireland, and Europe), Washington State Ferries (operating in the US state of Washington), and British Columbia Ferry Corporation (operating in the Canadian province of British Columbia).

Ferry Vessel Safety

"Vessel safety consists of the safety of a vessel and the safety in the operation of a vessel" (Costas book, second ed., 2010, p. 533). The safety of a vessel is concerned with whether a vessel adheres to construction, design, or technical standards and is therefore seaworthy. A vessel may become unsafe during its operation, if it incurs an accident—an unexpected and undesirable event.

"Although ferry incidents exist in North America and Europe, transportation by ferry is one of the safest forms of travel in these parts of the world" (Leach, 2014), but not necessarily true in other parts of the world. The safety of ferry transportation in developing countries is a safety concern.

In April, 2014, the MV Sewol ferry capsized traveling from Incheon (South Korea) to Jeju (South Korea)—300 of the 500 or two-thirds of the passengers died (many of whom were students at Danwon High School near Seoul, South Korea) versus one-third of the crew (<https://www.ship.technology.com/features/featuretaking-action-on-ferry-safety-4379066/>). Some of the passenger deaths were attributed to passenger confusion about the ferry's emergency procedures (a fault of the ferry's crew). Crew and other passenger deaths were attributed to the size of the ferry's cargo load (more than twice the ferry's designated limit) that was not tied down properly (a fault of the ferry's operator). A general safety concern for ferries is human error by the crew while ferries are underway, for example, inattentiveness, poor judgment, and negligence.

Vessel instability is a safety concern for roll-on/roll-off ferries, since "the vessels have large holes that allow for the loading (roll-on) and the unloading (roll-off) of vehicles, thus precluding vertical watertight bulk heads that are standard features for most commercial vessels" (Yip et al., 2015, p. 112). If the bow and stern doors of roll-on/roll-off ferries are breached while the ferries are underway, water will enter the ferries, possibly resulting in the ferries listing and then sinking, contributing to passenger and crew deaths and lost vehicles and cargo.

Ferry Vessel Accidents in the US Waters

Commercial vessel accidents that occur in the US waters and investigated by the US Coast Guard are classified into various types of accidents, that is, (1) fire/explosion (where a fire or explosion is the initiating event in causing a vessel accident); (2) collision (occurs when a vessel strikes or is struck by another vessel on the water surface); (3) allision (occurs when a vessel strikes a stationary object on the water surface); (4) grounding (occurs when a vessel comes in contact with the waterway's bottom or a bottom obstacle); (5) material-failure (typically involves equipment failure onboard a vessel); and (6) maneuverability (occurs when the maneuverability of a ferry vessel is negatively affected). Ferry vessel accidents are further discussed in Loeb et al. (1994).

The number of commercial ferry vessel accidents of a given type as a percent of the total number of commercial ferry vessel accidents (1795) that occurred in the US waters during the 11-year time period 2001–08 and investigated by the US Coast are presented in Table 1. The material-failure type ferry vessel accident has the largest percentage of total ferry vessel accidents for a given type of ferry vessel accident at 44.6%, followed by the maneuverability ferry vessel accident at 30.0% and the allision ferry vessel accident at 6.6%.

Table 1 Ferry vessel accidents in the US Waters 2001–08

Type of accident	Percent of ferry vessel accidents by type
Fire	1.2
Collision	1.4
Allision	6.6
Grounding	4.7
Material failure	44.6
Maneuverability	30.0
Other	11.5

The average number of crew injuries and passenger injuries per ferry vessel accident for commercial ferry vessel accidents that occurred in the US waters during the 11-year time period 2001–08 and investigated by the US Coast Guard were 0.028 and 0.191, respectively (Yip et al., 2015, p. 114). The former study also found that the number of ferry-vessel passenger injuries are positively related to the number of crew injuries, suggesting that enhanced and effective safety training for ferry-vessel crew members can have a positive impact on reducing the number of ferry-vessel accident passenger injuries.

Ferry Vessel Security

Actions taken by the US Coast Guard to secure the operations of ferries in the US waters include conducting boat escorts of ferries and stationing armed Coast Guard personnel in key locations aboard ferries (to ensure that ferry operators maintain control of their ferries). The US Customs and Border Protection (CBP) also inspects foreign-flag ferry vessels that arrive in or bound for the US port).

The security of BC ferries of British Columbia (Canada) is promoted by the Royal Canadian Mounted Police, Transport Canada, the Ministry of Transport and other stakeholders by (1) providing identification cards for ferry vessel employees, (2) designating restricted and prohibited ferry control areas, (3) random canine screening of ferry vehicles and baggage, (4) closed-circuit television monitoring, (5) security awareness training for all employees, and (6) waterside screening.

Ferry terminals are equipped with ramps that enable vehicles to be loaded and unloaded simultaneously from two decks of a ferry. Figs. 1 and 2 are images of ferry vessels.

In the study by Talley (2002), determinants of the number of fatal and nonfatal injuries in ferry vessel accidents that occurred in the US waters during the 11-year time period 1981–91 are investigated. The study concludes that the expected number of fatal injuries is 3.35% higher for fire/explosion than for collision, material/equipment failure, or grounding ferry vessel accidents. The expected number of nonfatal injuries is 3.60% and 4.46% higher for collision and fire/explosion ferry vessel accidents, respectively than for material/equipment failure or grounding accidents. The results suggest that “policies that reduce fire/explosion ferry-vessel accidents are likely to be efficacious in reducing both fatal and non-fatal ferry injuries” (Talley, 2002, p. 337).

Cruise Ships

A cruise ship is a passenger ship used by passengers for pleasure voyages that include the voyages themselves, ship amenities and sometimes calling at different ports as part of the passengers' experience (https://en.wikipedia.org/wiki/Cruise_ship).

When cruise ship passengers disembark from a cruise ship at the same cruise marine terminal at which they boarded the cruise ship, the cruise ship voyage is not a transportation voyage, since a distinction cannot be made between a passenger's origin cruise marine terminal and a passenger's destination cruise marine terminal. If the origin and destination cruise marine terminals differ, the cruise ship voyage is a passenger transportation voyage.

Cruise-Ship Sizes

The demand for cruise-ship voyages and the sizes of cruise ships have increased over time. The world's largest cruise ships (greater than or equal to 200,000 gross tonnage in size) in service or under construction are found in **Table 2**. Cruise ships exhibit economies of ship size at sea, that is, as cruise ships increase in size, cruise ship's transportation cost per passenger-transported declines—where the number of passengers transported is the maximum passenger carrying capacity of the ship.

Cruise Ship Safety

Cruise ships are subject to safety inspections that address fire safety, crew training, and proper functioning of all ship safety systems and lifesaving equipment. Cruise ships are required to have lifeboats (or rafts) and life preservers for every person on board. Safety regulations are monitored under the US and maritime laws. The US Coast Guard conducts safety inspections of cruise ships that sail from the US ports (Landry and Kling, 2018; <https://landryking.com>).

Cruise Ship Accidents in the US Waters

The number of ocean cruise vessel accidents of a given type as a percent of the total number of ocean cruise vessel accidents (263) that occurred in the US waters during the 11-year time period 2001–08 and investigated by the US Coast Guard are found in

Table 2 World's largest cruise ships

<i>Ship</i>	<i>Cruise line</i>	<i>Year placed in service</i>	<i>Gross tonnage^a</i>	<i>Maximum passenger capacity</i>

Table 3 Cruise ship accidents in the US Waters 2001–08

<i>Accident type</i>	<i>Percent of ocean cruise ship accidents</i>	<i>Percent of river cruise ship accidents</i>
Fire	7.6	1.2
Collision	5.7	3.6
Allision	4.6	15.7
Grounding	6.1	7.2
Material failure	26.2	32.5
Maneuverability	18.6	21.7
Other	31.2	18.1

Source: Yip, T.L., Jin, D., Talley, W.K., 2015. Determinants of injuries in passenger vessel accidents. *Accid. Anal. Prev.* 82, 112–117.

Table 3. The number of river cruise vessel accidents of a given type as a percent of the total number of river cruise vessel accidents (83) that occurred in the US waters during the 11-year time period 2001–08 and investigated by the US Coast Guard are also found in **Table 3**.

Material-failure type accidents represent the largest percent (at 26.2%) of ocean cruise ship accidents that occurred in the US waters and investigated by the US Coast Guard, followed by maneuverability accidents at 18.6% and then fire accidents at 7.6%. As for ocean cruise ship accidents, material-failure and maneuverability river cruise ship accidents (**Table 3**) also represent the largest and second largest percent, respectively, of river cruise ship accidents that occurred in the US waters and investigated by the US Coast Guard, but at the higher percentages of 32.5% and 21.7%, respectively. The percentages of allision and grounding river cruise ship accidents at 15.7% and 7.2%, respectively, also exceed those for ocean cruise ship accidents but the percentages of fire and collision river cruise accidents are less than those for ocean cruise accidents.

The number of ferry-vessel (ocean-cruise ship, river-cruise ship) passenger injuries in ferry-vessel (ocean-cruise ship, river-cruise ship) accidents occurring in the US waters (investigated by the US Coast Guard) is positively related to the number of ferry-vessel (ocean-cruise ship, river-cruise ship) crew injuries occurring in ferry-vessel (ocean-cruise ship, river-cruise ship) accidents (Yip et al., 2015, p. 116)—suggesting that enhanced safety training of ferry-vessel (ocean-cruise ship, river-cruise ship) crew members can have a positive impact on reducing the number of passenger injuries in ferry-vessel (ocean-cruise ship, river cruise ship) accidents.

Cruise Ship Security

Actions taken to secure the operations of cruise ships in the US waters include (1) pre-cruise, (2) boarding, (3) preparing-to-sail, and (4) during-the-cruise actions. Pre-cruise actions include the screening by the US authorities, for example, by the US Homeland Security and Immigration, of the names of all passengers that will be boarding cruise ships in the US waters. During the boarding, all check bags are scanned and passengers must pass through an airport-style detector. With respect to preparing-to-sail, the International Convention of Safety of Life at Sea (SOLAS) requires that cruise ships hold a muster drill within 24 h of embarkation that consists of passengers familiarizes themselves with the muster station for their particular ship level in case of an emergency. During the cruise, the ship captain and staff oversee the security operations for the ship. The Cruise Vessels Security and Safety Act requires all the US vessels to report crimes and missing persons immediately and collect evidence (following strict procedures).

Glossary

CAFE Corporate Average Fuel Economy Standards, the fuel economy standards implemented in the United States in 1975. Historically, the policy involved meeting separate standards for cars and light trucks, but since 2011, the standards have also been based on each vehicle's footprint.

EPA Environmental Protection Agency, one of the two organizations involved in setting and enforcing CAFE standards in the United States (the second is the Department of Transportation).

Footprint A measure of vehicle size approximately equal to the product of wheelbase (the distance between the front and back axles) and the average front and back track widths. The US standards were changed to differ by vehicle footprint in an effort to remove the incentive for manufacturers to meet CAFE standards by making their vehicles smaller. In other countries that use attribute-based regulations, the standards often differ by weight.

Gruenspecht effect The tendency for fuel economy standards to defer scrappage for used vehicles, increasing the average age of vehicles in the entire fleet. The standards raise the price of new vehicles, especially those that are largest and least efficient. With higher new vehicle prices, some potential buyers will not buy a new vehicle, but instead either hold on to their current vehicles longer or purchase used vehicles instead. This in turn also raises the price of used vehicles, which means that some used vehicle owners will find it worthwhile to repair or otherwise hold on to used vehicles for longer, raising the overall age of vehicles in the fleet.

Light trucks One of two categories of passenger vehicles regulated by fuel economy standards, where the other is cars. Light trucks are a subset of trucks with a gross vehicle weight rating of 8500 lbs or below. They are built on distinct frames from cars. Common categories of light trucks are vans, pickups, and sport utility vehicles (SUVs). They are particularly popular in the United States.

NHTSA National Highway Transportation Safety Administration, which is under the US Department of Transportation and is the other of the two organizations involved in setting and enforcing CAFE standards in the United States (with EPA).

Rebound effect The response to improved energy efficiency that tends to reduce the energy savings associated with the efficiency improvement. In this context, the rebound effect most commonly discussed refers specifically to the additional percentage increase in driving that occurs in response to increased efficiency of vehicles (and, therefore, lower fuel costs per mile of driving).

VMT Vehicle miles traveled.

Introduction

Following the 1973 oil crisis, policymakers around the world sought to reduce foreign oil dependence and began to consider regulating the fuel economy of new vehicles. First implemented in the United States in 1975 as Corporate Average Fuel Economy (CAFE) standards, similar policies were put in place soon after in Japan and later, in Australia, Canada, China, the European Union, and South Korea (Anderson et al., 2011). The policies encourage automakers to improve fuel efficiency by setting average fuel economy or fuel intensity levels (in miles per gallon or liters per kilometer) that their fleet or a subset of their fleet must meet

Figure 1 The red line indicates the level of the CAFE standard for cars (in miles per gallon). The dotted vertical line indicates the end of an aggregate standard for cars and the introduction of footprint-based standards. After 2010, we present two illustrative standards: the one in green shows the standard for a 42-square foot vehicle (in the 10th percentile of footprint size) and the one in blue shows it for a 50-square foot vehicle (approximately the 90th percentile).

each year. In countries where the standard is nonvoluntary, enforcement involves fines based on the extent of the manufacturer's deviation from the standard and the scale of their sales. Another commonality shared by the policies is that all have been dogged by concerns that the improved fuel economy will come at the expense of safety. Because the US policy has both the longest history and the largest body of research, the following chapter devotes the most attention to the effects of CAFE standards on safety. But we should note that many of the key findings emerging from the literature are broadly relevant to fuel economy rules worldwide.

Historically, CAFE standards were distinct for cars and light trucks, a category of vehicles that includes vans, pickups, and sport utility vehicles (SUVs). The intent behind this distinction was to differentiate between vehicles with different uses and users, though as light trucks have become increasingly popular as consumer vehicles, this feature of the policy has become more significant. For cars, the fuel economy standard increased gradually from 1978 to 1990, after which it was held constant. The 2007 Energy Independence and Security Act (EISA) introduced new and higher standards beginning with model year 2011 based on vehicle footprint. Vehicle footprint is a measure of vehicle size approximately equal to the product of wheelbase (the distance between the front and back axles) and the average front and back track widths. Larger footprints face less stringent standards. In 2018, the Trump administration proposed reductions in the 2021–25 standards. Fig. 1 shows the standards for cars since 1978.

The light truck standard has also changed over time. Between 1979 and 1982, separate two-wheel drive and four-wheel drive standards were in place, but from 1982 to 1991, firms could choose between separate standards or a combined standard. A single standard was in place from 1992 to 1996, after which it remained constant until 2005. The 2007 EISA further raised light truck standards while also incorporating footprint-based distinctions. The historical trajectory of light truck standards is shown in Fig. 2.

Other countries have designed their standards differently. In Japan, diesel and gasoline vehicles face separate standards that vary according to weight class. Both the EU and Chinese regulations do not distinguish between fuel types or vehicle classes (car versus light truck) but are differentiated by weight.

Figure 2 Initially, light-truck standards were different for two-wheel drive (shown in yellow) and four-wheel drive (shown in green), though starting in 1982, producers were allowed to choose between the separate standards and a combined standard, which eventually was the only standard. The dotted vertical line indicates the end of an aggregate standard for light trucks and the introduction of footprint-based standards. After 2010, we present two illustrative standards: the one in blue shows the standard for a 47-square foot vehicle (in the 10th percentile of footprint size) and the one in purple shows it for a 69-square foot vehicle (the 94th percentile).

Mechanisms

In order to understand how fuel economy rules can affect vehicle safety, it is helpful to first examine how automakers can respond to the regulation. A useful framework is to examine responses based on the time frame over which they can occur.

In the shortest term, vehicle producers can reduce the price of more efficient models and increase the price of less efficient models, a practice called mix shifting. This incentivizes purchasers to choose more efficient vehicles, bringing up the average fuel economy without directly changing the attributes of individual vehicles. If existing efficient vehicles tend to be smaller and lighter, this will reduce the average size and weight of vehicles sold. The downside of this approach for automakers is that it may reduce sales of their most profitable vehicles.

Over the medium run, producers can make adjustments to vehicle attributes. Moderate vehicle redesigns occur every 4–5 years, and fuel economy can be affected by trading off attributes along the existing technological frontier (Klier and Linn, 2012). For instance, it is well known that there is a tradeoff between horsepower and vehicle efficiency; reducing horsepower or making other engine modifications that reduce cylinders used at low speeds can improve vehicle efficiency without fundamental innovations. Likewise, weight and efficiency tend to be inversely correlated. Using lighter materials, removing heavy components, and redesigning the interior cabin can all reduce weight and thereby improve fuel economy. Much of the discussion around CAFE's effect on safety has long involved concerns about the consequences of this vehicle down-weighting. On the other hand, weight and footprint can be manipulated under weight- or footprint-based standards (Whitefoot and Skerlos, 2012; Gillingham, 2013; Ito and Sallee, 2018). Both direct attribute adjustment to meet a given standard and the manipulation of attributes to fall under different standards can have size and safety implications.

Finally, over the long term, automakers can develop a new technology. According to Klier and Linn (2012), this occurs on a decadal time horizon and involves changes such as implementing hybrid powertrain technology. With these kinds of innovations, it may be possible to improve efficiency while maintaining vehicle weight and horsepower, although it is possible that by directing innovation toward fuel economy, automakers may put less effort toward innovation in attributes that affect safety (positively or negatively).

Changes along each of these margins have occurred after the implementation of fuel economy standards. Goldberg (1998) estimated that CAFE was reducing the price of domestically produced compact and subcompact cars while increasing the price of all other classes. It is also well documented that vehicle weight dropped following the introduction of CAFE standards. For example, Anderson and Auffhammer (2014) note that vehicles became approximately 1000 lbs lighter between 1975, when the standards were introduced, and 1980. In one of the seminal papers on CAFE and safety, Crandall et al. (1989) estimate that 50%–80% of the observed weight reduction immediately following CAFE was attributable to the standards. Using a much longer time series, Bento et al. (2017) find that in aggregate, a 1 mpg increase in the standard reduced mean vehicle weight by 32 lbs, though the magnitude of the effect differs by initial weight. Based on a more theoretical approach, Jacobsen (2013) identifies the shifts in fleet composition implied by the stringency of the standard for different vehicle categories and finds that CAFE imposes shadow taxes on heavier vehicle categories within the car and light truck classes. Finally, technological innovation has occurred since the onset of CAFE standards. Klier and Linn (2016) find that following changes in the US and European standards, the rate of technology adoption among vehicle manufacturers increased.

Safety Effects

This discussion focuses on the effect of fuel economy standards on safety through four primary mechanisms: modification of vehicle attributes and, in particular, weight and size; changes in driving behavior in response to improved fuel economy; and changes in purchasing behavior that affect the age of vehicles on the road.

Changes in vehicle attributes can have different effects depending on the type of collision and the fatalities or injuries considered. It is useful to distinguish collisions into (at least) three types: single-vehicle collisions; multi-vehicle collisions; and collisions between vehicles and pedestrians, cyclists, and motorcyclists. In these latter two cases, one may measure the effect of a vehicle trait on safety for the occupants of that vehicle versus on safety for the individual(s) with whom the vehicle collides. Some research further distinguishes between multi-vehicle collision geometry (e.g., head-on collisions versus front-to-side collisions), though we generally abstract from that level of detail.

Vehicle Weight

The effect of vehicle weight on safety depends both on the physics of momentum and collisions and on human choices. There is no fundamental physical reason for lower weight to increase fatalities in the aggregate. The most significant factors in safety conditional on a collision are the magnitude of deceleration experienced and the penetration of the vehicle. Changes in vehicle mass have implications for the former (while changes in vehicle footprint may affect the latter). In the case of a single-vehicle collision, large vehicles are more likely to displace a smaller object (e.g., a tree or other barrier), reducing the deceleration

experienced by the occupant of the vehicle. For a simple model of a head-on, multi-vehicle collision^a, the vehicles change their velocities by

$$\Delta v_1 = \frac{m_2}{m_1 + m_2}(v_1 + v_2),$$

$$\Delta v_2 = \frac{m_1}{m_1 + m_2}(v_1 + v_2).$$

Hence, the change in velocity experienced by a vehicle is decreasing in the ratio of its own weight to the weight of the other vehicle (Joks et al., 1998; Greene and Keller, 2002). This suggests that proportional down-weighting of vehicles should not affect fatalities from multi-vehicle crashes. Relative mass may also be important in understanding collisions between a vehicle and a pedestrian, biker, or motorcyclist, where the latter categories can, as White (2004) memorably put it, be thought of as “ultralight vehicles.”

Using recorded crash data, much of the empirical literature of the past three decades has been consistent with the underlying physics. In single-vehicle crashes, there is mixed evidence that weight affects fatality risk^b. Kim et al. (2006) find no evidence, while NHTSA analyses suggest that down-weighting cars and light trucks by 100 lbs would increase fatalities from rollovers and fixed-object collisions by almost 500/year (Kahane, 1997, 2003). Bento et al. (2017) find the opposite result that lower mean weight reduces fatalities in single-vehicle collisions. In all cases though, the number of fatalities relative to the scale of the down-weighting is small.

The relationship between vehicle weight and pedestrian, bicyclist, or motorcyclist (henceforth referred to as pedestrian) safety has also been difficult to characterize. NHTSA analyses have consistently found that down-weighting the smallest cars increases pedestrian fatalities by 3+%, while weight changes across heavier cars and light trucks do not have a statistically significant effect (Kahane, 2003, 2012). There is not a fundamental reason that reducing weight among the lightest vehicles would increase danger to pedestrians, but this result may be explained by small vehicle configurations, driver sorting, or pedestrians behaving differently around smaller cars (i.e., behaving less cautiously because of lower perceived risk). Other studies, comparing pedestrian fatalities from collisions with cars versus light trucks, find that fatality rates are 77%–82% higher for light trucks (and serious injuries increase, as well) (Anderson, 2008; White, 2004). This may be due more to nonweight characteristics, however, as Anderson and Auffhammer (2014) find no statistically significant increase in pedestrian deaths for a 1000-lb weight increase when a light truck indicator is included.

With respect to multi-vehicle collisions, empirical studies generally agree that fatality risk depends on the relative weights of the colliding vehicles (Kim et al., 2006). Specifically, fatality risk to the driver is decreasing with the size of his or her own car and increasing with the size of the other car (Anderson and Auffhammer, 2014; Broughton, 2008, 2012; Evans, 2001; Tolouei and Titheridge, 2009). Notably, these results highlight a key externality: choosing a larger vehicle reduces own risk (at least in a multi-vehicle collision) but increases the danger to others. Many discussions of the effect of vehicle weight on safety wrongly conflate the internal decision-making rule with the net internal and external risks imposed by weight.

Thus far, the discussion of weight and safety has focused on how a change in weight affects the fatality risk conditional on a collision. But to understand the societal effects of a change in weight, it is necessary to calculate the expected risk, which depends on the frequency of collisions involving vehicles of different weights. That is, under a given scenario, how does the probability of a collision between vehicles of size x and size y change? The NHTSA analyses look at the effect of 100-lb weight reductions applied to each subset of vehicles, and while effects vary from study to study (as methodology and included model years vary), it generally appears that only down-weighting the smallest vehicles affects fatalities (with an observed increase of 1%–3%) (Kahane, 1997, 2003; Wenzel, 2012, 2013). More commonly, studies have examined how changes to the fleet that alter the variance of the weight distribution affect societal risk. Anderson and Auffhammer (2014) conclude that it would require a large and uneven downsizing of vehicles to increase overall fatalities by 1% or more. There are a number of studies that quantify the change in fatality risk associated with increasing (White, 2004) or decreasing (Buzeman et al., 1998) the variance of vehicle sizes within the existing fleet. In the British context, Tolouei and Titheridge (2009) examine the relationship between mass and fatalities over time and show that the individual benefits of additional mass vary over time as the size distribution of the fleet changes. Noland (2004) comes to a similar conclusion in the United States, finding that the apparent safety benefits of additional weight became less pronounced over time as the smallest vehicles stopped being produced.

To directly understand the effect of fuel economy regulations on fatalities, then, requires focusing directly on how the policies affect the distribution of vehicle weights in addition to the average effect. Jacobsen (2013) estimates the fatality risk associated with collisions between different vehicles and the effect of historical CAFE levels on market shares for different vehicle types. This is challenging because different types of drivers, such as very safe or risky drivers, may sort into different types of cars and drive in different locations and thus may encounter a different set of drivers around them as well as more or less safe road conditions (Coate and VanderHoff, 2001). Jacobsen addresses such sorting in a model and ultimately determines that each increase in mpg in the standards results in 149 additional fatalities. That is, the shift to smaller vehicles within both cars and light trucks without large shifts between the categories results in increased fatalities. However, Bento et al. (2017) directly document the effect of CAFE on both

^a If the vehicles collide at an angle, the equations are similar, but account for a two-dimensional speed vector.

^b This is distinct from the differential fatality risk associated with cars versus light trucks.

mean weight and weight dispersion and find that even though CAFE increased weight dispersion, the reduced mean weight and sorting of vehicles have a larger, mitigating effect so that in aggregate, CAFE reduced fatalities.

Vehicle Size

While much of the discussion about vehicle size focuses on mass, vehicles consist of a bundle of attributes, some of which tend to be highly correlated. Thus, empirical analyses of the effect of mass may actually be measuring the effect of these other correlated attributes. For instance, heavy vehicles tend to have a higher center of gravity, which increases the probability of a rollover (Li, 2012). Similarly, because heavier vehicles are often taller, their front ends hit the passenger compartment of smaller cars rather than the frame, hitting the upper bodies and heads of the car occupants rather than the crumple space, the area in front of the car intended to absorb impact. These same features likely affect safety outcomes in collisions with pedestrians, as well. The taller front ends of light trucks, in particular, are more likely to crush pedestrians, whereas in collisions with cars, pedestrians may be hit only in the legs and land on the softer hood (White, 2004).

Both of these factors—the high-center-of-gravity-induced rollover risk and dangerous collision geometry associated with tall front ends—would tend to result in overestimates of the risks associated with additional mass. However, perhaps the most important attribute that tends to be strongly associated with weight is footprint or size. One way that automakers can make vehicles lighter and more efficient is by making the vehicles physically smaller. Often, this involves reducing the crumple space, which manages the energy of the crash (Jokschi et al., 1998). When studies have included footprint as a distinct control variable, it tends to limit the effect of mass on fatalities, though these estimates are imprecise due to the high degree of collinearity between mass and volume (Khazzoom, 1994; Jokschi et al., 1998; Kahane, 2012). Relatedly the earlier puzzle of low-weight cars increasing pedestrian fatalities may be explained by the shorter hood; with less hood space, pedestrians' heads are more likely to hit the windshield, with adverse consequences (Kahane, 2003).

Since 2012, the US has had footprint-based standards in part to discourage shifts to smaller vehicles^c. However, this structure incentivizes firms to produce larger vehicles^d, and these incentives may be larger for light trucks than for cars (Whitefoot and Skerlos, 2012). If that is the case, the footprint-based standards would tend to increase the dispersion of vehicle weights, with adverse safety consequences. These results are not certain, however Jacobsen (2013) found that a footprint-based standard had smaller safety effects than an extension of the status quo CAFE, though the cost of meeting the standard would be higher. The precise implications of these new US standards—for safety and for the policy's stated goals—remains an open question.

At the same time that many passenger cars were becoming smaller and lighter in order to adhere to CAFE standards, light trucks were gaining a foothold as passenger vehicles. Many of the concerns about the external risks of heavy vehicles apply to light trucks (Toy and Hammitt, 2003; Gayer, 2004; White, 2004; Anderson, 2008; Fredette et al., 2008; Li, 2012), and certain features of light trucks may make them more dangerous than cars, even conditional on weight (Latin and Kasolas, 2002; Jokschi et al., 1998). However, the extent to which CAFE standards are responsible for the increased demand for light trucks is difficult to show, and there is only an imperfect correlation between increasing standards and the shift toward light trucks.

It is true that, as Figs. 1 and 2 show, the light truck standards have historically been lower than the car standards. It is thus possible for automakers to switch a car model to a light truck chassis to meet the lower standard, avoiding the imperative to improve fuel economy while introducing safety risks to other vehicles that might collide with the light truck (Bento et al., 2017). There are several high-profile examples of the use of this loophole, including the Chrysler PT Cruiser, introduced in 2001, and the Subaru Outback, modified in 2004. The former, which looks and drives like a car but is built on a light truck bed, was determined by NHTSA to be a light truck, and its sales helped bring Chrysler's light truck fleet into compliance with CAFE. The latter, originally sold as a sedan, was modified to be on a light truck chassis, so that vehicles with turbochargers, which hurt fuel economy, could be added to the Subaru fleet and the automaker would still be CAFE compliant.

VMT Rebound Effect

In addition to changing vehicle attributes in ways that may affect traffic fatalities, CAFE may also affect the number of miles people drive. By making the fleet more efficient, the regulation reduces the cost per mile of driving, incentivizing people to drive more—a rebound effect (Gillingham et al., 2016). Estimates of the magnitude of this rebound effect differ across time and context; the extent of the rebound depends on factors such as public transit availability, urban form, and the salience of changes in fuel costs. While estimates cover a wide range, Gillingham (Unpublished) finds that the average vehicle miles traveled (VMT) rebound effect in the recent literature from the United States is 8%–14% (depending on the relative weight put on more reliable odometer-based studies), which means that additional driving erodes 8%–14% of the initial fuel savings from the improved fuel economy from CAFE standards.

There are several issues with applying existing estimates of the rebound effect to the fuel economy context. First, most estimates of the rebound effect in the literature are based on how VMT change in response to changes in gasoline price. The extent to which the rebound effect with respect to fuel prices is the same as the rebound effect with respect to fuel economy is also a matter of debate.

^cThis is due to some extent to the fact that domestic vehicle manufacturers produce larger vehicles and have argued that they were unfairly hurt by CAFE standards.

^dIo and Sallee (2018) show that manufacturers respond to attribute-based efficiency standards in Japan by manipulating weight.

Additionally, these estimates are often based on short- or medium-term responses to price changes; fuel economy policy may have an impact over decades, which might allow for larger responses. Third, the extent to which driving decisions vary based on cost depends on wealth and congestion; as these factors change, the observed rebound effect may be less accurate. Fourth, as noted in the mechanisms section, fuel economy standards can be met via changes to vehicle attributes; if these changes make driving less appealing—for instance, by reducing horsepower—there may be less of a rebound. Another mechanism involves the addition of new, potentially expensive technology to vehicles to improve their performance, which would tend to increase the cost of new vehicles, producing an income effect and reducing the ability to pay for additional miles.

Despite these caveats, it is widely accepted that fuel economy standards would involve a rebound effect. This increase in driving would, all else equal, increase the probability of collisions. The simplest way^e to calculate this effect is to estimate a baseline fatality rate for each model year per cumulative VMT over the life of those vehicles and to combine this rate with the additional miles driven as a result of rebound. In their evaluation of the SAFE rule, which proposes freezing fuel economy standards at 2020 levels, NHTSA and EPA find that the incremental planned increase would result in 6340 additional deaths due to the rebound effect (under the assumption of a 20% effect; if the true effect is half of that size, it would result in 3170 additional deaths) (DOT, 2018).

On the other hand, the *ceteris paribus* assumption may not be reasonable. In response to increased risk, drivers may choose to drive more cautiously. The increased driving may contribute to congestion so that collisions, while more frequent, would occur at lower speeds and thus, with a lower probability of fatalities. This aspect has not yet been quantified to the best of our knowledge.

Vehicle Age

A final channel through which fuel economy policy may affect vehicle fatalities is by keeping old vehicles on the roads. This effect, first documented by Gruenspecht (1982), operates as follows. The standards raise the price of new vehicles, incentivizing buyers to purchase used vehicles instead, which in turn raises the price of used vehicles and can cause some owners of used vehicles to hold onto them for longer. Vehicle manufacturers may be especially likely to either raise the price or alter the attributes of their least efficient vehicles. Thus, the higher price and lower scrappage rates can be particularly pronounced among the lowest fuel economy vehicles. Jacobsen and van Benthem (2015) estimate the used vehicle price elasticity of scrappage and estimate the consequences of a hypothetical more stringent CAFE standard applied between 2010 and 2025, finding that, in terms of leakage (fraction of expected gasoline savings that are lost due to change in scrappage behavior), the Gruenspecht effect is larger than the rebound effect: on the order of 13%–16% of expected fuel savings from a fuel economy policy are lost due to the delayed scrappage of older, inefficient vehicles.

Beyond the consequences for fuel use, the Gruenspecht effect also affects safety. First, older vehicles may work less well. For example, if the brakes fail, collisions involving an older vehicle become both more likely and occur at a higher speed, increasing fatalities conditional on a collision. Second, over the history of fuel economy policy, many safety innovations have been introduced. A requirement that all vehicles include seatbelts took effect in 1968^f, meaning that at the onset of CAFE, some used vehicles that faced delayed scrappage lacked the technology. Airbags, while first installed in some cars in the 1970s, were not required in passenger cars until 1997 and in trucks until the following year. Other technologies, such as anti-locking brake systems or electronic stability control, have also become widespread or even required over the CAFE era, and technologies such as forward collision warnings or crash-imminent braking are increasingly common.

Each additional year a used vehicle lacking one of these technologies remains on the road, the risk of fatalities is increased. Recent NHTSA analysis has documented this effect: the proportion of occupants killed in fatal collisions is strictly increasing in model year age, with the proportion among the oldest model year group (18+ years) twice as high as the proportion among new (0–3) model years, though some of this is due to driver behavior (NHTSA, 2018). On the other hand, older vehicles tend to be driven less. If an older fleet translates to fewer vehicle miles traveled, this may have some offsetting safety benefits, as indicated by the earlier discussion of VMT.

Conclusion

Fuel economy standards have often been critiqued for having negative consequences on traffic safety. Concerns have primarily focused on the use of down-weighting to improve vehicle efficiency and the presumption that smaller cars are intrinsically less safe. From a societal perspective, it is not evident that fuel economy policy-induced changes in vehicle weight reduced safety. There is a general consensus that historically, CAFE contributed to a reduction in vehicle weight and that this reduction disproportionately affected smaller vehicles (though this may no longer be true with footprint-based standards). However, the net effect on traffic fatalities is ambiguous due to the directionally uncertain effect of vehicle weight on single-vehicle fatalities, and the sorting of vehicles by weight within the United States. The effect of CAFE on vehicle footprint, which is highly correlated with weight, also has

^eThis simplification is not without its limitations. The rebound effect may differ across drivers in ways that systematically relate to either their car choices or their location, which would bias the estimated fatalities.

^fThe presence of seat belts in all seating positions was mandated by NHTSA under Title 49 of the United States Code, Chapter 301, Motor Vehicle Standard No. 208. This is distinct from a requirement that passengers wear seatbelts, though regulations mandating seatbelt usage are on the books in all states except New Hampshire.

safety implications. Much of the historical down-weighting involved reductions in vehicle size, and there is some evidence that safety is increasing in vehicle footprint conditional on weight. Furthermore, the regulations may have motivated innovations in light trucks, whose popularity tended to increase the variance of vehicle weights and which may have unique safety disadvantages for those with whom they collide.

While less often discussed, two other consequences of CAFE likely reduced road safety. First, the improved fuel efficiency reduced the cost of driving, incentivizing an increase in VMT. With more driving, collisions and fatalities likely increased. However, it is important to note that this increased driving is not merely a cost—it also improves the welfare of those who are able to drive more than they previously could afford. Second, by changing the costs and attributes of new vehicles, CAFE policy affected the used vehicle market, keeping older cars on the road for longer. These older cars, which may lack the latest safety innovations, are likely less safe than the new vehicles that would have been bought in their absence.

Considerable research has documented the effect of fuel economy standards on safety via these channels. There are also several papers that examine the consequences of fuel economy improvements for traffic fatalities from a more macro viewpoint, by examining the relationship between these variables over time and space. Using state- or national-level variation and controlling, to varying degrees, for safety innovations and demographics, these papers generally did not find much of a relationship between CAFE and traffic fatalities (Noland, 2004, 2005; Ahmad and Greene, 2005). These small effects may reflect the limited safety consequences of fuel economy standards or the challenges of time series analysis with relatively little variation and many confounding factors.

Ultimately, while much is known about how historical fuel economy standards affected weight, footprint, driving behavior, and fleet age, many questions remain to be answered by future work. For instance, there is little work on how footprint-based standards affect safety by leading automakers to upsize vehicles. There is also much room for more analysis on the effect of fuel economy rules on safety outside of the United States. Such future work can help guide policymaking on fuel economy for years to come.

Hazardous Materials Transport

Introduction

Hazardous materials (or dangerous/hazardous goods/substances) are materials that pose a risk to the health and safety of people, living organisms, and/ or the environment. A hazardous material often is a chemical that is prone to reactions with a negative external effect, such as a fire, a toxic cloud, or an explosion.

Mankind has come a long way in its use of hazardous materials, which forms a diverse mix of various materials, which are used for different applications. Hazardous materials can be used as a fuel (gasoline, natural gas), as raw materials for other products (polymers, rubber, fertilizers, plastics), or simply as day-to-day materials used in everyday life (car fuels, cleaning materials). They are produced, stored, and transported from production facilities to their clients and end-users and as such form an important part of our everyday lives and our economies. At the same time, these materials pose a risk to their surroundings due to their intrinsic hazardous nature and as such, these risks need to be managed properly. Although the American DOT and the European Eurostat on average “only” list several dozen casualties per year for their respective territories, transport of hazardous materials is something to be taken very seriously as some of the examples in this section will show.

This section will therefore touch ground on a number of elements that are relevant for transporting hazardous materials, such as the modes of transport that are used for transporting hazardous materials, their respective risks, and some basic aspects of the different transport modalities. We will also give a very general overview of international rules and regulations. Finally, we will give a non-exhaustive overview of challenges and discussions that are currently taking place in academia.

Modes of Transport

There are different modes of transport through which hazardous materials are transported. Each mode has its own specific challenges, risks, and examples of disasters. Here we will briefly discuss air, rail, road, and water transport (in alphabetical order). Obviously, hazardous materials can also be transported by pipelines, but as a mode of transport, this is not included here as there is also a dedicated section to pipeline transport of hazardous materials in this work.

Air

Air transport is not generally associated with large bulk quantities of hazardous materials, but is mostly associated with smaller quantities, or specific materials, such as infectious items, ammunition, and radioactive materials. Specific attention is paid to lithium batteries as these can develop enormous amounts of heat in seconds as well as toxic fumes when not properly handled or in case of production errors. Examples of this are the UPS airlines flight 6 crash in 2010 and the mysterious missing of flight MH370 in 2014, which was also linked to lithium ion batteries, although the wreck remains unfound as of April 2019.

Rail

Rail transport of hazardous materials has a number of challenges concerning routing, risks, and alternatives for the transport. Statistically, rail transport is a very safe mode with a very good track record. Nevertheless, there have been very serious disasters and incidents, such as in Ryonchon, North Korea (2004), Graniteville, USA (2005), Viareggio, Italy (2009) and Lac Megantic, Canada (2013). What makes this transport specifically interesting from a risk management point of view is that transport—although certainly not in every country or region to the same extent—runs on tracks that are also used for passenger transport and as such run through densely populated areas. Diverting transport around densely populated areas often is not possible as rail networks are less branched than road networks, for example. This means that alternative routes from A to B, apart from the shortest or fastest route can be scarce and less attractive from a logistical or cost point of view.

Tank wagons are roughly 2–3 times the size of tank truck and a train may transport large bulk quantities for a specific client, as well as different materials altogether (ranging from different hazardous materials to mixing hazardous materials with non-hazardous materials). Hence, the transported amounts may be enormous and could have a larger impact altogether, if several wagons are inflicted at the same time (e.g., in the Lac Megantic disaster, where 63 tank wagons of a 74 wagon train carrying crude oil exploded or burned excessively), or when the materials of one wagon (e.g., carrying flammable liquids) may inflict damage to another wagon carrying hazardous materials (e.g., flammable gases) which may cause an even greater disaster. The potential lethal effects of rail accidents with hazardous materials vary from several dozens of meters (in case of a pool fire), up to 150 m (in case of an explosion of flammable gasses) to over a kilometer (in case of a toxic gas).

Road

Road transport is a common and visible way of transporting hazardous materials. For example, for transporting fuels for cars and trucks, but also for transporting bulk of other materials in the industry, or in smaller non-bulk quantities (e.g., in boxes or drums). In history, there have been many examples of incidents with road transport of hazardous materials. In 1978, for example, over 200 people were killed in Los Alfaques, Spain after a Boiling liquid expanding vapor explosion (BLEVE) occurred at a camping site. More recently in 2018, a BLEVE occurred on a road near Bologna, Italy.

From a risk management perspective, the difference from rail transport is that road transport is often directed around cities and other populated areas. This of course leaves out the fact that supplying gas stations often leads to trucks entering densely populated areas. Also, there are many more road trucks than rail cars and road trucks interact with other traffic much more often than rail transport, which increases the potential for accidents and negative consequences. Moreover, an incident with a truck often leads to more significant spills than is the case with rail transport. A final substantial element of road transport of hazardous materials is that transport through tunnels causes significant risks for other traffic. This is due to the nature of tunnels where the confinement of space leads to other effects than in the open air. Infamous is the 1982 gasoline truck explosion in the Salang tunnel in Afghanistan, which may have caused up to 2700 fatalities and could be the deadliest road incident ever recorded. Other tunnel disasters, such as in the European Mont Blanc Tunnel (1999) and Gotthard Tunnel (2001) did not involve transport of hazardous materials (instead, the disaster in the Mont Blanc Tunnel involved flour and margarine) indicate that even when there are non-hazardous materials involved, incidents in tunnels may have enormous effects.

Water

Here we need to distinguish between inland and sea transport. Transport of hazardous materials by ships leads to different risks than by road and rail. In most cases, the distance between the transport of the hazardous materials and the adjacent area is larger than with rail and road transport. This leads to lower risks as the effect of an incident leads to less (or no) casualties. Nevertheless, bulk sea transport (e.g., tanks with toxic chemicals) or oil tankers still pose a significant environmental risk. In case of a disaster, such as a collision or sinking with a loss of containment, this may lead to large environmental disasters, such as infamous disasters the *Odyssey* and the *Exxon Valdez* spills in 1988 and 1989, respectively or more recently the *Sanchi* oil tanker collision in 2018.

These different modes of transport all have their own respective history of disasters, challenges, and risks. This had led to the development of different rules and regulations with the aim of creating a basic level of safety, as well as developing a clear regulatory framework for all involved stakeholders. We will elaborate the most important international rules and regulations in the following section.

Rules and Regulations

There are many different roles involved in transporting hazardous materials, from shippers, manufacturers, producers, carriers, governments, and emergency responders to civilians and workers. Each of them have different interests and are affected differently. People living near transport routes wish to live safely, while carriers could wish to minimize costs and governments carry responsibility for maintaining a general level of safety. Through the years and often in response to major disasters, different rules and regulation have been implemented. To ensure a level playing field and minimum requirements concerning the safety of transport, general requirements are applicable to the transport of hazardous materials. Here we will touch base of some of the important and dominant international rules and regulations.

General Arrangements for All Transport Modes

The committee of experts on the transport of dangerous goods of the United Nations Economic and Social Council (ECOSOC) has adopted the UN recommendations on the transport of dangerous goods (also known as the Orange book). The UN recommendations are contained in UN model regulations, which aim to present a basic scheme of provisions for all modes of transport (except oceanic bulk tankers) that will allow uniform development of national and international regulations governing the various modes of transport. As such, they are not mandatory, but have gained widespread international acceptance and are transcribed in national and regional legislation and regulation.

The model regulations cover principles of classification and definition of classes, listing of the principal dangerous goods, general packing requirements, testing procedures, marking, labeling or placarding, and transport documents. These include requirements concerning the construction and material and product testing.

An important aspect herein is the marking and labeling. The model regulations therefore adopted nine different classes of hazardous materials, each with different subcategories, to characterize the risks of different chemicals. The classes are:

Class 1: Explosives. Divided into six subcategories ranging from explosives with a mass explosion hazard to extremely insensitive, this class contains explosives, such as TNT, nitroglycerine, consumer fireworks, and ammunition.

Class 2: Gases. This class distinguishes between flammable (e.g., butadiene, methane, hydrogen), non-flammable (e.g., carbon dioxide, helium, nitrogen), and poisonous gases (e.g., chlorine, ammonia). These gases can be transported in different phases, such as compressed or liquefied. Apart from being flammable or poisonous, gases can also be asphyxiants or cryogenic.

Class 3: Flammable liquids. This class is subdivided into three packing groups depending on their boiling and flash point. This class contains liquids, such as gasoline, kerosene, and diesel.

Class 4: Flammable solids. Flammable solids are materials that are either flammable and ignite easily (e.g., cellulose nitrate or magnesium), spontaneously combustible and will ignite when in contact with oxygen (e.g., white phosphorus) or dangerous when wet (these are substances that will emit flammable gases or will react when in contact with water, such as potassium, cesium, or sodium).

Class 5: Oxidizing agents and organic peroxides. These substances are not necessarily combustible, but may cause, or contribute to the combustion of other material by yielding oxygen (e.g., ammonium nitrate). Organic peroxides are thermally unstable substances, which may undergo exothermic self-accelerating decomposition (acetone peroxide).

Class 6: Toxic and infectious substances. Toxic substances (class 6.1) are classified for being harmful or able to cause serious injury or death if swallowed, inhaled, or by contact with skin (e.g., pesticides). Infectious substances (class 6.2) are biohazardous substances, classified for containing pathogens, including bacteria, viruses, parasites, or other agents, which can cause disease in humans or animals upon contact. Medical waste also falls under class 6 materials.

Class 7: Radioactive substances. These are substances, such as uranium, plutonium that are subject to radioactive decay and as such emit ionizing radiation.

Class 8: Corrosive substances. These are substances, which will cause severe damage when in contact with the living tissue, or will materially damage, or even destroy, other goods, such as metals. This class is divided into an acid subclass (e.g., hydrochloric acid) and an alkalis subclass (e.g., potassium hydroxide).

Class 9: Miscellaneous. Substances and articles, which during transport present a danger, not covered by other classes, such as asbestos, seatbelt pre-tensioners, and some lithium batteries.

Each of the aforementioned classes comes with its own labels and placards (as shown in [Fig. 1](#)). In addition, hazard identification numbers (or Kemler codes) and the UN numbers are used to identify materials that are being transported. When transporting hazardous materials, tank wagons must be fitted with orange plates bearing the hazard identification number (here, "33") and the UN number ("1203"). The hazard identification number includes four numbers that indicate the nature of the transported material, while the UN number gives the exact identification of the goods. The hazard plate shown in [Fig. 2](#) indicates that a highly flammable liquid (33) is being transported, and that this liquid is petrol (1203).

This system of classification, listing, packing, marking, labeling, placarding, and documentation is meant to simplify transport, handling, and control as well as increased uniformity and clarity in dealing with incidents. This should, in general use, create more safety and let carriers, consignors, inspecting authorities, and of course the public, benefit from more safety.

Arrangements Per Transport Mode

Hence, the UN model regulations form the template for regulating the transport of hazardous materials. Competent authorities (e.g., the Chinese Ministry of Transport, the DOT in the United States, the ACTDG in Australia, or the European Commission) may modify model recommendations for State/region specific regulations. Each modality has its own specific requirements that are described in their specific regulations:

Air transport: Individual airline and governmental requirements are incorporated by the International Air Transport Association (IATA) to produce the widely used IATA dangerous goods regulations (DGR). This manual is the global reference for shipping dangerous goods by air and the recognized standard by airlines.

Rail transport: For all ground transport, the UN model regulations are leading. However, local or regional regulations may apply. One such pan-continental regulations concerns the development by the Organization for International Carriage by Rail (Organisation intergouvernementale pour les Transports Internationaux Ferroviaires; OTIF), an intergovernmental organization of 50 European, African, and Near Eastern states, of the international regulations concerning the international carriage of dangerous goods by Rail (the Règlement concernant le transport international ferroviaire de marchandises dangereuses, or RID). The RID has two annexes that create a framework to regulate the transport of hazardous materials between member states. The two annexes include:

1. Regulations concerning the merchandise involved, notably their packaging and labels (this is called Annex A).
2. Regulations concerning the construction, equipment, and use of vehicles for the transport of hazardous materials (this is called Annex B).

Road transport: Here as well, the UN Model Regulations are leading, although local or regional regulations may apply. As such, the *Accord Européen relatif au transport international des marchandises Dangereuses par Route* (ADR) is also important to recognize. The ADR states that with the exception of certain exceptionally dangerous materials, hazardous materials may, in general, be transported internationally in wheeled vehicles, provided that two Annexes be met, which basically have the same scope as the two Annexes for rail transport: Annex A regulates the merchandise involved, notably their packaging and labels and Annex B regulates the construction, equipment, and use of vehicles for the transport of hazardous materials.

Moreover, the ADR Secretariat has defined a classification system for major tunnels in Europe. The categories are based on the idea that there are three major dangers that may cause numerous victims or serious damage to the tunnel structure, namely explosions, release of toxic gases, or the release of volatile toxic liquids and fire. Each national authority is responsible to categorize its tunnels in classes ranging from A (least restrictive), to E (most restrictive).

Water transport: In case of sea transport, the UN Model Regulations do not apply. Instead, the International Maritime Organization (IMO) has developed the International Maritime Dangerous Goods Code ("IMDG Code", part of the International Convention for the Safety of Life at Sea) for transportation of dangerous goods across seas. The IMDG Code lays down basic principles and a number of recommendations for good operational practice and on how to handle individual substances, materials, and articles. This includes advice on terminology, packing, labeling, stowage, handling, and emergency response action concerning hazardous materials. The provisions in the IMDG Code are directed at the mariner, but also affect

industries and services, such as manufacturers, packers, shippers, and port authorities. IMO member countries have also developed the hazardous and noxious substances by sea convention (HNS Convention) to provide compensation should there be a spill of dangerous goods in the sea. For inland shipping, other rules and regulations may apply. Since 2008, for example, the European agreement concerning the International Carriage of Dangerous Goods by Inland Waterways (Accord Européen relatif au transport des marchandises dangereuses par voies de navigation intérieures, or ADN) applies to inland shipping of hazardous materials. The ADN contains among others provisions concerning dangerous substances and articles, provisions concerning their carriage in packages and in bulk on board inland navigation vessels or tank vessels, as well as provisions concerning the construction and operation of such vessels.

Challenges

There are a number of challenges concerning the transport of hazardous materials. There are many publications that give interesting overviews of the challenges facing transport of hazardous materials. We will here address a number of these challenges in a non-exhaustive manner.

Challenges Concerning Risk Assessment

Each mode of transport has its challenges concerning managing the inherent risks related to the transport. It can however be stated that there is a considerable body of knowledge on quantitative risk assessment (QRA). QRA's generally follow three steps: (1) hazard and exposed receptor identification; (2) frequency analysis; and (3) consequence modeling and risk calculation (Bedford and Cooke, 2001). The result is a numerical assessment of the risk and consequences. Consequences are mostly seen in terms of casualties (number of people affected), but can also be expressed in economical or ecological damage. In terms of casualties, the outcome can be expressed in two ways: first there is the individual risk. This is the annual probability that an unprotected person will die as a result of an accident involving hazardous materials at a certain spot if that person resides there for a full year. The risk is visualized on a map by dots, which act as spatial contours. Due to the impact of a large disaster, not only individuals are affected, but also groups of people are affected. In such cases, we talk about societal risk (or group risk). This is the cumulative probability for each year that at least 10,100, or 1000 people die as a direct result of their presence in the influence area of an establishment or transport route if an incident happens with hazardous materials. This is visualized on a logarithmic scale by using the fN curve, where f represents the frequency of an accident and N the number of people expected to die as a result of that accident. This feature allows that quantitative risk assessments are often used to model a specific situation (e.g., a rail track through a dense urban area) and identify the risk level, which can then be related to norms or standards and test whether certain situations are allowed. Nevertheless, a clear problem exists in assessing the risks of transport of hazardous materials. This is due to the fact that there are relatively little accidents, which results in little reliable statistics due to little empirical reviews of accidents, their causes, effects, and dispersion of hazardous materials (Erkut et al., 2007; Erkut and Verter, 1998). Other critiques on QRAs often concern the technocratic nature, that models and people modeling the same situation generate various outcomes and that models are simplified depictions of reality that do not generate absolute truths, but should be used as decision support.

Qualitative risk assessments deal with the identification of possible accident scenarios and attempts to estimate the undesirable consequences. Qualitative methods are, for example, event tree and fault tree analysis or consultation of experts. Not only are these assessments often necessary when reliable data to estimate accident probabilities and consequence measures are scarce or missing, it also allows for more tailor-made solutions in practice. The goal is to identify events that appear to be most likely and those with the most severe consequences, and focus on them for further analysis or identify risk mitigation measures to limit the possibility of certain specific scenarios from occurring. This makes that qualitative risk assessments are often preferable to quantitative risk assessments to mitigate specific scenarios (Van der Vlies, 2011).

Low Probability High Impact

Transport of hazardous materials is often seen as low probability high impact risks. This means that the chances of an accident are slim, but the effects may be enormous (Jonkman et al., 2003). It can therefore be quite difficult for decision-makers to base policy and management on extreme scenarios that have a very small chance of occurring, but with enormous effects. One of the worst-case scenarios generally associated with the transport of hazardous materials transport, for example, is a BLEVE. In this scenario, a vessel or tank containing a liquid or pressurized gas instantaneously ruptures after the temperatures of the material have reached a level above their boiling point, for example by an external heat source (fire). In order to control the effect, a larger distance from the source to the adjacent area is effective, but also next to impossible in dense countries. These countries often implement a risk-based policy (Erkut et al., 2007; Van der Vlies, 2011). When a decision-maker wishes to have an effect based policy and minimize the effect of a potential disaster, this leads to rerouting transport axes and divert them from city centers and other dense areas. In some countries, this may be an effective policy but this also leads to large costs. As mentioned before, for water transport there often already is a larger

distance from the source to populated areas, which decreases the potential effect on humans. Of course a spill by, for example, an oil tanker may lead to a large effect area and impact marine life.

Terrorism

In recent years, a growing concern involves the use of transport of hazardous materials as a potential terrorist weapon (Erkut et al., 2007; Milazzo et al., 2009). This is not only due to general terrorist threats around the globe, but also after a devastating explosion in Toulouse France in 2001 was linked to a terrorist attack, as well as a failed terrorist attack on a French chemical plant in 2015. It is of course very difficult, if not impossible, to predict an attack. There are, however, attempts to identify risks associated to these threats and how to mitigate and predict them.

Safety Culture and Human Factors

Luckily, the standards as mentioned earlier in the international rules and regulations, have made all transport of hazardous materials modes relatively safe. Nevertheless, having good policies and standards leaves out the fact that there are humans interacting with technologies and rules. This leads to the notion that safety culture is an important concept and is often described as the environment within which individual safety attitudes develop and persist and safety behaviors are promoted. In general, safety culture can be defined as the collection of the beliefs, perceptions, and values that employees share in relation to risks within an organization, such as a workplace or community. Recent decades show a vast body of knowledge on this subject. After incident analyses of large disasters such as the space shuttle challenger disaster, the Piper Alpha oil platform explosion, and also several Korean air incidents, there are a number of risk factors that may lead to low(er) safety culture, such as a strong hierarchical organization in which subordinates do not dare to speak out to managers, profit over safety (if profit and revenue are more important than safety), fear of, for example, reprimands, and ineffective leadership (if leaders give the wrong safety examples). For more on this topic, see the Safety Culture chapter in this work.

Energy Transition

One of the major societal challenges is the transition toward a sustainable society. In the slipstream of the energy transition, there are also challenges concerning safety and transport of hazardous materials. The transition to less polluting fuels leads to a larger demand for compressed and liquefied natural gas (CNG and LNG). Although these fuels are not new, the increase of transport will lead to more risks. Especially the transition to a more hydrogen based economy and an influx in the use of hydrogen may lead to a large increase of demand and transport of hydrogen. What this will effectively mean for risks is not fully clear and also depends on the extent to which hydrogen will replace other fuels, where and how this is produced and of course how this will be transported from A to B.

Biography

Vincent van der Vlies is managing consultant at the Dutch consultancy firm Berenschot as well as guest researcher at the Institute for Security and Global Affairs of Leiden University. Vincent wrote a dissertation concerning the transport of hazardous materials by rail and how this affects urban planning in the Netherlands. In his career as a consultant, he performed dozens of studies concerning hazardous materials, as well as other safety and security-related methods ranging from incident analyses, political strategic risk management, big data safety analyses, and safety audits. To delineate this broad expertise, he studied subjects, such as hooligan-related incidents in professional football, security in cruise terminals and ships, the consequences of a no-deal Brexit and trains professionals in safety- and security-related topics.

Introduction

According to the United State's National Highway Traffic Safety Administration (NHTSA), a head-on crash "refers to a collision where the front end of one vehicle collides with the front end of another vehicle while the two vehicles are traveling in opposite directions." (NHTSA, 2015). By that definition, for a head-on collision to occur, two vehicles must meet one another in opposite directions on the same roadway. This requires a two-way road with no physical separation between opposite directions of travel. This could be either a single carriageway or a dual carriageway with a narrow median separation and no physical barrier that would prevent vehicles from crossing over to the other carriageway.

Head-on crashes are among the most severe of crashes due to kinematics. Crash severity is related to the combined speed of impact (Richards and Cuerden, 2009), which for head-on crashes is the sum of the speeds of the two vehicles at impact, rather than the difference in speeds for a rear-end impact, or the speed of the ramming vehicle for a side-impact crash. This is borne out by crash fatality statistics. According to NHTSA (2015), head-on crashes represented 10.2% of all fatal crashes in the United States in 2015, compared to 2.3% of crashes overall. Due to the nature of their occurrence, head-on crashes usually involve an innocent victim driver and occupants with little control to avoid the crash, and in many cases, occupants of the not-at-fault vehicle suffer more severe injuries (Wali et al., 2018).

The rest of this article will first discuss the physics of head-on crashes, including the physical and traffic conditions that give rise to head-on crashes and the physics of how severe they are. Next will be discussion of methods that have been proven to prevent the occurrence of head-on crashes, including infrastructure and technological solutions. Then will be discussion of methods to mitigate the severity of head-on crashes, including vehicle technology and behavioral interventions. Finally will come a summary of the ideas in the article along with conclusions and perspectives for future research.

Physics of Head-on Crashes

Road Conditions

As noted previously, by its definition a head-on crash can only occur on a two-way road with no physical separation between directions of travel. One vehicle must stray out of the lanes assigned for travel in its direction into the lanes assigned for the opposite direction of travel. This can happen either intentionally, typically when a driver is passing another vehicle, or unintentionally, due to a driver either being distracted, drowsy or impaired, or traveling too fast so they lose control and cross into oncoming traffic. Accordingly, narrow lanes and shoulders offer less forgiveness for straying out of lane unintentionally and recovering and are thus usually associated with higher numbers of head-on crashes (Qin et al., 2004). Smaller radius curves are also associated with greater propensity for drivers to stray out of their lanes (Xu et al., 2018). At the same time, a FHWA study of crash causality found wider lanes and shoulders and a higher speed limit to be associated with more opposite direction crashes on horizontal curves (Porter et al., 2018). This study also found an increasing radius of curvature to be associated with fewer opposite direction crashes. While wider lanes and shoulders offer more forgiveness for brief lateral straying from the travel lane, they also can encourage drivers to travel through a horizontal curve at higher speeds than the curve can be safely negotiated.

Restricted sight distance can be more of an issue for head-on crashes than it is for other types of crashes, due to drivers needing to see farther down the road for passing on two-lane roads. AASHTO (2018) recommends a minimum of 280 m of passing sight distance for roads with speed limits of 81 km/h and 440 m for a 130 km/h speed limit. Belz and Chang (2018) conducted a simulator

study examining driver behavior when passing on two-lane two-way roads. Among other things, they found that the presence of horizontal curves affects the distance participants required to pass another vehicle. In a country with right-hand traffic, drivers were less likely to pass when the road bended to the right than if it was straight, and more likely to pass when the road bended to the left. The required sight distance is greater at higher speeds, since both the passing and oncoming vehicle close in on one another at a faster rate.

Centerline markings can increase drivers' awareness of the presence of oncoming traffic in the adjacent lane and the attendant danger in crossing out of the lane. In particular, [Harrison et al. \(2016\)](#) found that painting a 1-m wide centerline in the center of two-lane two-way roads in Queensland Australia reduced casualties by 25%. At the same time, centerline markings can also give drivers more security about where their space on the road is, leading to higher speeds, unless lane or shoulder widths are reduced.

Traffic Conditions

In order for road conditions to result in a crash, the driver must necessarily make an unsafe action, either intentionally or unintentionally. Unintentional unsafe actions frequently occur due to a driver being unable to react appropriately to unexpected traffic conditions. This often happens because drivers are overstimulated by an abundance of external stimuli in the roadway environment in different locations relative to the driver, for example heavy oncoming traffic combined with intersecting roadways or a forested area with the possibility of wildlife entering the roadway ([Thiffault and Bergeron, 2003](#); [Heslop, 2014](#)). However, drivers can also be understimulated due to driver monotony, for example, when there are few if any other vehicles on the road and little possibility of conflict with other road users or wildlife. This can apply to head-on crashes, where with low volumes, drivers do not expect or prepare for meeting oncoming traffic. With high volumes, drivers can be overstimulated and not able to react in enough time to an oncoming vehicle crossing the centerline. Multiple studies that considered head-on or opposite direction crashes on segments separately from other multiple-vehicle crashes have found the rate of these crashes (crashes per vehicle-distance) to increase with traffic volume ([Qin et al., 2004](#); [Porter et al., 2018](#)).

[Arvin et al. \(2019\)](#) conducted a study of driver maneuver and response volatility, that is, variability moment to moment in driver actions such as steering and braking. They found speed, longitudinal and lateral acceleration volatilities to be highly associated with the frequency of head-on crashes. In particular, intersections with high-lateral volatility, that is, lane keeping, have greater risk of head-on collisions.

[Oviedo-Trespalcacios et al. \(2016\)](#) conducted an extensive literature review of distracted driving and operational impacts, including safety. They reported that distracted driving tends to result in reduced speeds. The effects on lane position are less consistent, but there is a difference between distracted and non-distracted conditions, which would be a precursor to head-on crashes. Activities requiring longer off-road glances, such as text messaging rather than talking on the phone, resulted in greater crash likelihood, and the longer the glance away from the road, the higher crash risk. Given that deviation from proper lane position is a common result of distraction, reducing driver distraction of any kind would be important for reducing head-on crashes.

Severity of Head-on Crashes

Head-on crashes resulting from direct hits have higher severity than those that result from impact on an oblique angle. [Jurewicz et al. \(2016\)](#) report that head-on crashes with a direct hit, that is, when the angle between the colliding vehicles is 180 degrees, have a critical injury speed of 48 km/h (30 mi/h) for the striking vehicle, 80 km/h (50 mi/h) for rear end crashes. Opposite turning crashes, or those hitting not direct can vary up to 64 km/h (40 mi/h).

A higher change in speed during the crash results in increased severity. [Richards and Cuerden \(2009\)](#) compiled data from crash reconstruction studies in Britain, examining the relationship between the delta v (change in speed pre-crash to collision) and the severity of the outcome (fatal, severe or slight injury). For head-on crashes, a change in speed of about 30 km/h (20 mi/h) results in a fatality 10% of the time. At about 55 km/h (35 mi/h), it is 50%; and a change of about 80 km/h (50 mi/h) is 90% fatal.

[Deng et al. \(2006\)](#) investigated how physical characteristics of the roadway affect the severity of head-on crashes. They found that while a wider roadway reduces the severity, wet pavements and high density of access points both increase the severity. Nighttime crashes are also more severe than crashes during daylight hours.

Vehicle mass and mismatched bumpers are issues related to crashes between heavy vehicles and SUVs or pickup trucks with passenger cars. [Acerno et al. \(2004\)](#) studied records in the Seattle Crash Injury Research and Engineering Network database to investigate the impacts of crashes between passenger cars (PVs) and light duty trucks (LTs), including SUVs and pickup trucks. Occupants in passenger cars experiencing frontal crashes are far more likely to be killed than those in light duty trucks, due not only to the differences in vehicle mass but also bumper heights. In their sample, four out of 19 in passenger cars were killed, none in LTs were killed. Of the 15 who survived, 14 sustained serious injuries, compared to only three of the fifteen in LTs. These results are consistent with those reported by [IIHS \(1999\)](#), in which the relative risk of death for occupants of PVs involved in frontal collisions with LTVs is 3–4 times greater than those involved in similar collisions with another PV.

Prevention of Head-on Crashes

Infrastructure Solutions

A simple and long-running solution to reducing the number of head-on crashes on two-lane two-way roads is to implement no passing zones in locations with insufficient sight distance for passing. [AASHTO \(2018\)](#) provides recommended minimum sight distance requirements for passing based on design values for perception reaction time, assumed differential speed with the vehicle being passed, and a desirable buffer distance after completing the passing maneuver. No passing zones can also be implemented in locations that experience frequent head-on crashes, or when traffic volumes are high enough that passing is not practical.

A head-on crash can also occur when a driver travels the wrong way on a divided or one-way roadway. This most commonly happens when a driver inadvertently enters a freeway using an offramp rather than an onramp. Such drivers are frequently intoxicated or otherwise not fully aware of the surroundings, missing the warning signage that is required for such conditions in traffic regulations set by road jurisdictions (in all developed countries and most developing countries as well) ([FHWA, 2009](#)). [Finley and Miles \(2018\)](#) describe an evaluation of countermeasures aimed at reducing the incidence of wrong way driving, primarily due to intoxicated drivers. They conducted an experiment on a closed course to evaluate the visibility of a variety of wrong way warning options, including larger than usual signage, retroreflectivity, and flashing digital lights on the sign edges, as well as mounting the signs at both normal (2.14 m, or 7 ft, off the ground) and reduced (0.61 m or 2 ft) heights. They also evaluated retroreflective pavement arrows indicating the correct direction of travel. Participants were asked how difficult it was to identify the signs in darkness at varying levels of intoxication; they reported that the retroreflectivity and digital blinking lights improved visibility, though the effect was not significant.

Another approach for reducing head-on crashes is aimed at reducing inadvertent crossing of the centerline. Various highway agencies have tried to do this using centerline rumble strips between the lanes of opposing traffic. [Persaud et al. \(2004\)](#) describe centerline rumble strips as “either raised or grooved patterns, installed perpendicular to the direction of travel, that produce audible and tactile warnings when traversed by vehicle tires.” They analyzed data for 210 miles of treated roads in seven US states before and after installation of centerline rumble strips. They found a combined reduction of 14% for all injury crashes, and a 25% reduction in frontal opposing-direction sideswipe injury crashes. [Babineau and Fontaine \(2018\)](#) describe the findings from an implementation of centerline rumble strips by Virginia Department of Transportation. They found a reduction of 42% in head-on, opposite direction sideswipe, and fixed object, off-road crashes on curves with design speed of 55 mph or less. For all road sections irrespective of curvature, the reduction in these crashes was 35%.

In some locations, centerline rumble strips are either not practical or insufficiently effective. Rumble bars are an alternative audible warning device for these situations. Rather than depressed in the pavement-like centerline rumble strips, rumble bars are raised above the pavement, constructed of thermoplastic, and installed along with the centerline pavement markings ([Wu et al., 2018](#)). An implementation of rumble bars on 189 miles of rural two-lane highways in Texas found a reduction of 21.3% of all single vehicle run off road and opposite direction crashes, and up to a 40% reduction for injury crashes of those types.

Rumble strips and rumble bars are useful for warning drivers when they are about to cross into oncoming traffic, but they do not prevent such centerline or median breaches. More effective is to install a physical barrier between opposing lanes of traffic. A cost-effective solution is cable barriers designed not to stop the vehicle instantly, but to prevent a full breach into the opposing traffic. Cable barriers have been used effectively to reduce median crossovers on divided highways ([Kirsch et al., 2018](#); [Eustace and Almothaffar, 2018](#); [Srinivasan et al., 2017](#)). These barriers effectively eliminated virtually all median breaches and reduced 80% of fatal and injury crashes ([Eustace and Almothaffar, 2018](#)). [Srinivasan et al. \(2017\)](#) estimated a benefit cost ratio of up to 8.28. The findings indicated universally that cable barriers do their job—median crossover crashes are converted to collisions with the cable barrier, which have much lower severity.

Cable barriers have also been used on rural two-lane two-way highways to eliminate head-on crashes. These installations are generally done without substantial widening of the centerline, only enough to construct the barrier. [Xian et al. \(2019\)](#) describe an evaluation of an installation of cable barrier along the centerline on two-way two-lane expressways in rural areas in Japan. They found this treatment virtually eliminated crossover crashes, though crashes into the barrier still occurred. Widening the interior striping adjacent to the cables reduced contact with the cables. On average 6.6 poles were damaged in each crash with the cable barrier, requiring 50 min of road closure time to repair.

A drawback of cable barrier installation on rural two-lane two-way highways is that the oncoming lane can no longer be used for passing. In situations where accommodating passing is desirable and there is sufficient pavement width, the pavement can be restriped to provide two lanes in one direction and one in the other, with the two directions separated by a cable barrier to prevent vehicles from crossing over. The split between 2 and 1 lanes alternates periodically along the road. This has come to be known as a “2 + 1 road” ([TRB, 2003](#)). [Fig. 1](#) shows an example of a 2 + 1 road in Sweden, the country in which the concept was first implemented. Many rural highways had been built in Sweden with 13-m (43 ft) wide pavements over the period from 1955 to 1980, typically with two 3.5 m (11 ft) lanes and two 3 m (9.8 ft) shoulders. The shoulders were intended to serve as emergency stopping areas, but instead, drivers began to use them for overtaking, or as a place to move over when vehicles were overtaking from the opposite direction. The resulting confusion about what drivers expected from one another led to the decision to implement the 2 + 1 concept. Early trials found not only an improvement in safety but also in operations, with the setup making it easier to overtake other vehicles. As of 2000, more than 1000 km (620 mi) of these roads have been converted to the 2 + 1 concept, all with cable barriers. These 2 + 1 roads have also been implemented in Portugal, Germany (without barriers), Finland, Russia (without barriers), Romania (no barriers), Estonia, Lithuania, New Zealand, and the USA (https://en.wikipedia.org/wiki/2%2B1_road#cite_note-2).

Vehicle Technology Solutions

Many motor vehicle manufacturers have begun to implement systems on their vehicles to partially automate the driving task. The intention for these systems is to assist the driver with routine aspects of the driving task, and especially to catch when the vehicle encounters a potentially hazardous situation. One such type of system is known as lane keeping assist or lane departure alarms. These systems either take over the steering of the vehicle to keep the vehicle within the lane in which it is traveling, unless a turn is signaled, or simply sounds an audible warning when the vehicle drifts out of the lane. Some systems do both.

Sternlund et al. (2017) describe an evaluation of the ability of these kinds of systems to reduce injury crashes in Sweden. They used an induced exposure method to compare crash data for Volvo passenger cars that were equipped with these systems with those that were not using them. The investigated 1853 driver injury crashes from the Swedish Traffic Accident Data Acquisition database (STRADA), including 146 cars equipped with lane departure warning and 11 equipped with lane keeping assist. They found a 53% reduction in head-on and single vehicle crashes under non ice or snow conditions for the vehicles with these systems. Cicchino (2018) performed a similar study in the United States of vehicles equipped with lane departure warning and single-vehicle, sideswipe, and head-on crashes, using crash data from 25 US States for the years 2009–15. They found that vehicles with lane departure warning had significantly lower involvement rates in crashes of all severities (18%), in those with injuries (24%), and in those with fatalities (86%).

Another potential form of driver assistance technology is passing collision warning systems. These systems assist with passing maneuvers on two-lane two-way roads that require use of the oncoming traffic lane. Hassein et al. (2018) describe such a framework and algorithm design using radar sensors to identify how far away other vehicles are and how quickly they are closing in. A simulation in MATLAB was used to develop the algorithms that direct the driver when it is safe to cross into the opposing lane and when they need to complete their maneuver.

Mitigation of Head-on Crash Severity

In addition to preventing head-on crashes from occurring, efforts have been made to reduce the severity of head-on crashes when they unfortunately occur. This started with incorporating front crumple zones into the structural design of passenger cars. This concept was patented by an engineer for Mercedes-Benz, Béla Barényi, originally in 1937 and updated in 1952 (https://en.wikipedia.org/wiki/Crumple_zone). A crumple zone works by absorbing crash energy in the outer parts of a vehicle, thus preventing it from being transferred to the passenger compartment. This reduces deformation of the passenger compartment, mitigating injuries to the occupants. These principles are incorporated into the design of nearly all vehicles today.

Front airbags and restraint systems are another important development in vehicle safety systems. Also known as “supplemental restraint systems,” these are standard equipment in all vehicles today, and deploy upon detection of a front impact on the vehicle above a certain deceleration rate. Due to the explosive nature of airbag deployment it is critical for passengers to wear three-point seatbelts to avoid contact with the air bags while they are deploying. Kuk and Shkrum (2018) compared the occurrence of fatal injuries upon deployment of airbags with and without seatbelt use using data from 110 frontal and offset frontal crashes provided by the Office of the Chief Coroner for Ontario. They found that wearing seatbelts reduced the severity of injuries when airbags deployed, except for abdominal injuries.

As noted previously, crashes between heavy vehicles, especially tractor-trailer trucks, and passenger cars, when they happen, can be extremely serious, much more likely to be fatal than crashes between two passenger cars. In an effort to reduce the severity of such crashes, Friedman et al. (2018) proposed an external radar-activated airbag system that deploys on the front of heavy trucks. They

conducted simulation to demonstrate potential for substantial reduction in damage to passenger cars colliding with a truck that deploys such an external airbag system.

Conclusions

Head-on crashes between motor vehicles are frequently extremely severe due to the physics of how they occur. Numerous infrastructure and technology approaches have been implemented to prevent the occurrence of head-on crashes, with various levels of effectiveness. As well as reducing the occurrence of head-on crashes, efforts have been made to mitigate the severity of head-on crashes when they do occur, most notably in vehicle design improvements.

The most effective way to prevent the occurrence of head-on crashes is to eliminate the possibility of them occurring, for example with physical barriers separating opposing traffic flows from one another. Where that is not practical, it is effective to warn drivers when they are about to stray out of their lane into oncoming traffic, either using audible warning devices in the road or using automatic systems in the vehicle. Continued and more extensive deployment of all of these approaches will be invaluable for reducing the incidence of deaths on roadways worldwide.

The History of Life Saving Helicopters

The care and management of sick and wounded has always involved an element of transport. The sick and wounded must often be moved to allow for better care, and high-quality care can be brought to the patient. Choosing the right means of transport depends on many factors and can sometimes pose a challenge of its own.

Since the dawn of air transport, aircrafts have been used for medical transport to a variable degree. The first confirmed aeromedical transport dates back to 1915 and the transport of a wounded Serbian air force lieutenant from the frontline in Albania to safety. In the years to follow aeromedical transports by fixed wing aircraft occurred occasionally in different settings but often ad hoc and with a certain flare of heroism. The first organized service was established in 1928 and still exists today as the Royal Flying Doctor Service in Australia.

As with the first known transport in 1915, it was often armed forces and military conflicts that drove the development of aeromedical transport forward. The Korean War in the early 1950s marks a paradigmatic shift in that it introduced aeromedical transport by helicopter as a new and effective concept in the evacuation of wounded servicemen. This concept proved highly successful as it allowed airborne evacuation of wounded without being dependent on airfields. In the Vietnam War the addition of specially trained medical corpsmen added further improvement in survival rates. Contemporary research showed that wounded soldiers had better survival rates than civilian car accident victims on highways back in the United States, thanks to helicopter evacuation and the specially trained medics.

In other parts of the world the use of helicopters in air rescue grew out of the need for getting access to injured people in austere environments or remote areas. The Swiss Air Rescue was established as early as 1952 and was a merger of mountain rescue and aviators. The Swiss concepts of bringing care to the patient, wherever they are, developed quickly over the next years and soon became the inspiration and eventually the norm for similar initiatives in other European countries. In the 1970s, both in North America and Europe, several services of helicopter rescue were established, based on the experiences and early initiatives described earlier.

Following the early 1970s the number of helicopter emergency medical services (HEMS) grew rapidly in Europe and North America. Today HEMS is a part of the pre-hospital care system in all parts of the world and in most countries. In the United States, there are around 75 companies operating more than 1500 helicopters, and in Europe all but some of the minor countries have a HEMS in some shape or form. Let alone Great Britain has 22 different HEMS systems. The organization, staffing, and concepts vary greatly around the world. It seems, however, that no matter how HEMS is organized it plays an important role in pre-hospital care of critically ill and injured patients (Ringburg et al., 2009).

Do Helicopters Save Lives?

The early intention for establishing HEMS was to bring the patient quickly to hospital. Advanced care was only available in hospitals and quick air transport was superior to slow ground transport for the critically ill or injured. This was especially true in trauma patients, where the golden hour of trauma has been the norm for years; getting the severely injured patient to the hospital within the first hour is regarded as imperative to avoid the immediate pathophysiologic consequences of trauma and save lives. In Germany one

of the main reasons for establishing HEMS in the early 1970s was to have an extensive network of HEMS that could quickly respond to road vehicle accidents on the accident-stricken autobahn and transport the patient to a nearby trauma hospital.

With improved medical knowledge and technology, and better prevention of both causes and consequences of trauma and disease, previous lethal conditions are avoided or taken care of more effectively. The increasingly high competence of ground emergency medical services (EMS) also contributes to taking better care of patients before they arrive in hospitals. The impact and importance of the transport element in HEMS is therefore not as prominent as in the early days of HEMS. The effect that quick transport alone has on patient survival is also highly questioned in the medical community, especially after some studies have shown that trauma patients transported by civilian cars have better survival than those transported by ground EMS in some urban settings.

The positive effect HEMS has on survival in critically ill or injured patients is however well proven even in later years ([Andruszkow et al., 2016](#)). Denmark is a small country with an excellent infrastructure. For many years, the Danish pre-hospital system relied on ground EMS supplemented by physician-staffed ambulances that covered all of Denmark. The general opinion was that HEMS was superfluous in Denmark until a pilot project with a Danish HEMS showed a benefit of HEMS in certain patient groups, even in a system with excellent ground EMS cover and short transport distances to hospitals ([Hesselfeldt et al., 2013](#)). The effect is presumed to be found in quickly bringing high medical competence out to the patient in combination with quick transport to the hospital. Other studies have also pointed at the medical competence on-board as the one life saving factor that makes a difference between ground EMS and HEMS ([Lossius et al., 2002](#)).

The general opinion today is that helicopters alone do not save lives just because they represent a quick transport element. Helicopters with high medical competence onboard save lives by bringing hospital standard care quickly to the patient.

Safety Record of Helicopter Emergency Medical Services

The safety record of HEMS is tightly coupled with the safety record of the aviation industry per se. However, since the HEMS industry developed late as compared to the development of airplanes and helicopters, the technical safety standard has always been good, and very rarely have we seen accidents in HEMS caused by technical malfunction. Add to this that HEMS is often a phenomenon in high resource countries, the technical standard of the HEMS fleet is generally very good.

Pushing the limits or operating beyond the limitations of the flight equipment is, however, a more common cause that can be easily mistaken for a technical cause but is in essence a human factor issue. The two main reasons for pushing the limits seem to be the desire to do all possible to help, or to maximize profit in a system where the business plan is dependent on payment per mission or restricted by a tight budget.

Pushing the Limits

On November 24th 1987 a BO105C from the Norwegian air ambulance crashed in the Dovrefjell mountains in South Norway. The crew had been called to a mission to transfer a critically ill patient from one hospital to another in the evening after dark. Despite darkness, snow and poor visibility the crew accepted the mission and took off. Less than 10 min after take-off, the helicopter crashed in the mountains close to the base and all three crewmembers perished in the immediate fuel fire following the crash. The Accident Investigation Board concluded that the combination of darkness, snow showers and fog caused the pilot to lose visual references and eventually lose control of the aircraft. The use of strong search lights to aid orientation only contributed to the confusion in the snowy weather. Interestingly, the Accident Investigation Board did not comment on the obvious fact that the crew had accepted a mission despite poor flying conditions. In 1989 and 1991 the same HEMS base experienced two more accidents, one with fatal outcome for both the crew and the patient. In both accidents poor visibility was a contributing factor causing whiteout in the 1989 accident and collision with power lines in the 1991 accident. In the report of the Accident Investigation Board of the 1991 accident it was recommended that the company must pay attention to and follow up on attitudes of the crews on the HEMS base. The report also cited that the pilot had a "relaxed attitude towards rules and regulations that he himself did not regard as pressing." In later years it was confirmed by other crewmembers working at the same HEMS base that the general attitude was to have a low threshold for accepting missions even in poor flying conditions. The reason for this was the desire to justify the existence of the HEMS base by carrying out as many missions as possible. The operating company later introduced stricter regulations on flight operations minima to avoid similar accidents.

In the United States, the National Transportation Safety Board issued a special investigation in 2006 to address the high number of accidents in aviation emergency medical services, including HEMS and recommended operational strategies and technological improvements that would improve the safety record of the industry ([National Transportation Safety Board, 2006](#)). The three previous years before the report had seen an unusual high number of accidents in the HEMS industry with 41 crashes and 39 fatalities. Besides concerns about lack of technological equipment like terrain awareness and warning systems, the report addressed less stringent requirements for HEMS operations without patient on-board, lack of aviation flight risk evaluation programs and inconsistent flight dispatch procedures as recurring themes in the accidents investigated. In essence, the desire to provide medical care seemed to contribute to pushing the limits of the services, and internal procedures, risk management systems and equipment were not robust enough to compensate.

The high number of HEMS accidents in the United States also resulted in a considerable effort from the Federal Aviation Administration (FAA) that has resulted not only in better regulations but also better dialogue and cooperation between the

governing agencies and the industry. On reviewing all HEMS accidents in the United States between 1991 and 2010, the FAA concluded that 62 accidents could have been avoided with current regulations and industry standards potentially having saved 125 lives lost. A strong message from the FAA is that aviation safety decisions are separate from medical decisions (https://www.faa.gov/news/fact_sheets/news_story.cfm?newsId=15794). Accepting the medical need of a mission does not automatically mean accepting the mission. Flight safety cannot be compromised just because the mission has a high acuity or is of special value (e.g., pediatric trauma). Flight safety has precedence in all circumstances and the decision to fly or not must always be unaffected by the scope of the medical mission.

Technical Limitations and Improvements

The previous statement that technical issues have rarely been the cause of accidents in HEMS holds true but, in some cases, not adapting to new safety features or technical improvements in helicopter hardware have been known to cause accidents and near misses. There is still an ongoing discussion in HEMS communities on whether single engine operations are adequate or if dual engine operations should be the standard. In most industrialized countries, dual engine helicopters are the norm and, in some cases, even required for HEMS, but even in the United States there are still HEMS companies that operate with single engine aircraft. The differences between single engine and dual engine aircraft from a safety perspective are primarily in the aircraft's ability to perform safely during take-off and landing and handle engine failure in any phase of flight. Single engine aircraft are involved in the majority of HEMS accidents in the United States, today with around 75%, and this share has increased although the number of single engine aircraft in the HEMS service has decreased in the United States. This is a clear indication that dual engine aircraft are safer and should be the norm in HEMS.

Night vision goggles (NVG) were introduced in HEMS over the last 20 years to enhance operations during hours of darkness. Interestingly though it has never been shown that the number of accidents is higher during hours of darkness than during daylight. This might be contributed to the fact that not all HEMS systems operate during hours of darkness and that those who do have a higher vigilance during night flight. In this context, introducing NVG in HEMS has not contributed to reducing accident rates but has probably contributed to increasing safety margins during night flight. It may also have contributed to improving the regularity of HEMS in that NVG allows for better visual control and decision making during flight. Some pilots report that where they previously would have canceled or aborted a mission because of darkness, they now accept and continue because they have better visual control. Philosophically this poses a challenge since NVG in civilian HEMS was not supposed to push the limits of operations further but to enhance safety within existing operations. This is similar to an often-cited dilemma; do you drive faster with your seat belt on than you would without? So far, NVG does not seem to have influenced accident or incident statistics in any direction but it probably had a positive impact on regularity. Some services that previously operated only under daylight have been able to commence operations during night, thanks to NVG, thus improving the public's access to the service. HEMS operators must be attentive to the impact NVG operations have on their service and whether it increases safety margins by adding an additional safety layer to night operations or maintain safety levels by increasing regularity.

The implementation of other technical improvements in HEMS is slower than in for example, commercial fixed wing operations. HEMS operation is very often a weight versus range question where more technical equipment induces increased aircraft weight and thus reduced range. Coupled with the desire to maintain the aircraft small to allow access to patients this reduces the ability to adopt all possible and available technical improvements. New technical devices that enhance safety must therefore be weighed against their effect not only on safety but also on their impact on patient care and patient safety. With improved engineering, some equipment has become smaller and lighter thus allowing easier implementation.

Glass cockpit and electronic map systems are increasingly being implemented in new aircraft. Improved GPS technology allow for better navigational systems and autopiloting. New auto hover systems are available with zero GPS groundspeed, which is an excellent improvement to hoisting and search and rescue missions. Other technologies, such as weather radar, terrain awareness and warning systems, and traffic collision avoidance systems are also increasingly being implemented in new HEMS aircraft.

Developing Technologies

In 2014, an EC135 of the Norwegian air ambulance hit a power line on descent to an accident scene. The impact occurred at low air-speed and the installed wire cutter in the front of the aircraft did not perform as intended, but instead stretched the wire further until the main rotor impacted the wire and cut it. The wire snapped back at the aircraft damaging the main rotor pitch links thus the main rotor was in principle detached from the engine. This caused the aircraft to lose lift and fall 25 meters killing two of three crewmembers. The accident revealed an insufficient marking of all wires and lines that pose a threat to HEMS aircraft, in the available electronic map system. It also revived a demand for technology that can identify powerlines and other similar obstructions. Lines and wires are a highly relevant hazard in many HEMS systems especially in mountainous areas and have been known to cause accidents similar to the 2014 accident in Norway. The technology to identify wires is developing but still has not reached a reliable sensitivity to be implemented. In the meantime, map systems need to be accurate enough to contain all wires and threats to HEMS aircraft. This often requires manual tracking and logging that can be quite labor intensive but at the same time a necessity to maintain safe operations.

Icing is a challenge for HEMS, especially in the polar regions and also in tempered climate zones during cold season and can pose a severe restriction to operations in many areas especially during winter (Pulkkinen et al., 2019). The accumulation of ice on the

rotor during flight severely reduces the airfoil and efficiency of the rotor but the added weight of the accumulated ice on the airframe also impairs flight. In some cases, loss of view through the windshield has also been reported as a severe effect of sudden icing. Only very few accidents in HEMS have been directly related to icing. But icing can also be difficult to document post-accident. A Bell 407 operated by Mercy Air crashed near Mason City, Iowa in the United States in 2009 and icing is presumed to have been a major contributor to the accident. The airframe was consumed by fire following the crash and ice accumulation on the airframe could not be documented. However, reports from eyewitnesses at the scene confirmed that ice had accumulated on cars in the area and that roads were icy.

In risk areas the occurrence of icing is occasionally reported during flight and can often be solved by either landing or changing altitude. Being a severe hazard, it predominantly poses a restriction to service that affects the patient. For many years, deicing systems have been a standard feature of fixed wing aircraft and have eventually found its way to rotor wing aircraft. The rotor blades are the most vulnerable part of the helicopter in icing conditions and typically electrical systems have been implemented that heat up the leading edge of the rotor. These systems are however restricted to larger aircraft since they require relatively large and weight demanding hardware to operate. Most HEMS operate with small and middle-sized helicopters where this technology has not been implemented or is in a stage of development. Since the need for this technology is restricted to a very small proportion of the total number of aircraft produced, the helicopter manufacturers have also not prioritized the development of deicing systems for smaller aircraft. With developing technology and focus on demand, we should expect the development of better solutions for helicopter deicing in the future.

Balancing Flight Operations Decision Making With Medical Mission Needs

As stated previously, flight safety considerations and flight safety decisions should be made independent of the nature of the medical mission request or the development of a medical mission. On paper, this is reasonable but as history and experience has shown, this can be challenging.

HEMS crews mostly consist of one or two pilots and a medical crew. The interaction between the flight crew and the medical crew has different dynamics depending on company culture and standards.

Some companies have chosen to maintain a strict barrier between flight operations and medical operation, for example, keeping the pilot shielded from the medical mission planning. The pilots are not aware of the nature of the mission, the acuity or level of urgency and only concerns themselves with flight mission planning and execution. During flight the pilots are kept out of medical communication and do not monitor the development in the medical cabin. Some companies have taken this to the extent of physically shielding the cabin from the cockpit. However, shielding the pilots completely from the mission is not always possible and the stress of not knowing what is going on has (by few) been described as just as stressful as being involved.

In other HEMS systems members of the medical crew have flight operations duties, for example, to support the pilot during flight operations. In some countries, especially in Europe this is the core of an “integrated crew concept” where a HEMS paramedic acts as a pilot assistant during flight, and as the HEMS doctor’s assistant on ground. These HEMS paramedics have medical training but also flight operations training to enable them to assist the pilot in navigation during instrument flight rules (IFR) and night operations. This is a cost- and resource-effective way to run HEMS, as it not only avoids the need for two pilots, but also poses some potential conflicts of interest during a mission. The involvement in medical care of a critically ill or injured patient can be emotionally stressful and has the potential to influence decision making during flight. This influence is not restricted to the HEMS paramedic but also extends to the pilot. Especially in the integrated crew concept the pilot is expected to be a resource in missions on ground as long as it does not interfere with flight operations and -planning. This puts extra demands on the operating company to make sure that the medical aspects of the mission do not interfere with decision-making pre- or in-flight. Company training and culture must therefore be targeted toward this potential conflict and hazard. In Europe, the European HEMS and Air Ambulance Committee (EHAC) has developed a tailored crew resource management concept to meet this challenge; the aeromedical crew resource management course (<http://www.ehac.eu/acrm.html>). This crew resource management (CRM) course adheres to the European Aviation Safety Agency requirements for CRM training but adds the medical aspects of operations to address this factor in the decision-making and human factors.

Fatigue

Fatigue from lack of sleep or long working hours have been known to cause accidents in aviation. Fatigue causes reduced attention and reaction and can be a crucial component in an emergency situation during flight. The impact of fatigue on aviation safety has led to strict regulations on working hours and workload during duty to ensure that flight crews are rested and fit for flight. HEMS is especially vulnerable to fatigue, as there are large differences in workload in HEMS. Missions occur without warning and involve an unpredictable workload. The saying “hours of boredom and moments of terror” describes the workload or lack thereof in HEMS well. High workload can have just as much effect on the level of fatigue as long hours of standby and boredom. The aviation authorities in most countries dictate how HEMS can operate and the regulations are in most cases the same as for general civilian aviation. Whereas many HEMS systems restrict duty hours to 12-h shifts, some have longer periods of duty, in some cases up to a week. This is especially the case in remote locations or in low activity HEMS systems. In these systems, mandatory rest is imposed after a certain number of active working hours in a 24-h cycle or longer (Zakariassen et al., 2019). Recent research, however, suggests that counting only hours is not sufficient to avoid fatigue, for example, working at night time has a stronger effect on fatigue than

working during day time. Adding to this, humans are generally poor at assessing their own level of fatigue and often underestimate how tired they are. Preliminary results suggest that the effect of disturbed night sleep every night over a number of days induces a level of fatigue that requires at least 24-h of rest to achieve normal levels of attention and reaction. As a result, HEMS services that wish to maintain long on-call duty hours must implement fatigue risk management (FRSM) systems to closely monitor and act on fatigue. Crews are required to monitor themselves and have a low threshold for reporting own fatigue and act for example, going off duty or taking naps, resting, and avoiding other tasks besides mission. Part of the FRSM is also to educate and train crews to monitor their own fatigue and recognize when fatigue sets in. HEMS companies in many countries are currently challenged with finding the right balance between continuity in duty that affects mission readiness the least, and avoiding work schedules that have the potential to induce fatigue.

The Future Challenges of the Industry

The technological development in aviation is moving forward and new safety features and safety technology to both monitor and automate flight are being increasingly implemented. The rate of implementation is, however, strongly connected to the HEMS company's ability and willingness to implement new features. HEMS cannot regulate income the same way as civilian aviation by regulating airfares and often have to justify that new technology has a positive impact on patient care before air safety is addressed. Accidents are often the strongest driver to improve safety in HEMS not the prospective attitude to make flight operations as safe as possible at all times.

On the positive side, increasing regularity in HEMS seems a strong driver to implement new technology as it achieves better access to patients. GPS based points-in-space approaches are developed in many countries allowing HEMS to land at hospitals much the same way as passenger airplanes land on airports in poor weather conditions. IFR routes are increasingly implemented for HEMS specifically to allow flight between hospitals in poor weather and new technology is being developed to even allow for ad-hoc IFR landings on the scene. Whilst these new technologies improve regularity, they also push the boundaries of operations and can potentially contribute to putting HEMS in situations where the safety margins are very small and highly dependent on technology to stay safe.

Biography

Stephen J. M. Sollid is a medical doctor specialized in anesthesiology. He has worked as an HEMS physician in Norway since 2002 and is currently the chief medical officer of the Norwegian Air Ambulance Foundation. He has a PhD in patient safety and risk management from the University of Stavanger, is an Associate Professor of Prehospital Critical Care at the same university and teaches prehospital critical care at master and bachelor level at the university. He is involved in research on prehospital patient safety with over 30 peer-reviewed publications, and mentors several PhD and MSc projects.

Introduction

Knowledge about the relationship between road design and safety is continually evolving. Horizontal and vertical road geometry was always in the focus of the road design process due to its obvious implications on vehicle behavior stemming from the laws of physics. It is generally assumed that driving on a straight and flat road section is easier, while negotiating curves requires more driver efforts. Thus, road design guidelines have typically included sets of limitations on the extent of horizontal and vertical road curvature, related to road function and the design speed. Initially, the criteria for setting horizontal and vertical alignments of the roads were defined based on engineering judgment and life experience. The original approach relied on assumptions based on vehicle kinematics and drivers' ability to react to changing road conditions, and aspired to avoid extreme road design conditions that would increase the risk of loss-of-control of the vehicle and, hence, crash occurrences. Over the last decades, substantial developments took place in crash data analyses and evaluating safety effects of various road design conditions, providing quantified measures of the safety impacts of road geometry characteristics.

This paper summarizes current knowledge on safety impacts of horizontal and vertical road alignments. The horizontal alignment of a road comprises straight sections and horizontal curves that provide connections between the straight sections (tangents). Road design literature distinguishes between simple (or circular) curves, with a constant radius, and other forms of curves that combine various radii. The radius of a curve is the main characteristic of horizontal curvature that is examined in safety evaluations (other measures of curvature can be deflection angle, degree of curve, etc.). In addition, the basic concept of a horizontal curve considers forces acting on a vehicle negotiating a superelevated curve. According to the laws of mechanics, when a vehicle travels on a curve it is forced outward by a centrifugal force. This force is resisted by a superelevation force and a transverse friction force, which depend on vehicle weight and speed, side friction between the tires and the pavement, and superelevated structure of the road. Hence, a superelevation parameter can be among additional curve characteristics to be examined in the road safety context. Moreover, crash frequencies in a curve can be influenced not only by the characteristics of the curve itself but also by road characteristics in general, for example, length of a road tangent prior to the curve or overall road bendiness, which should also be examined in safety evaluations.

The vertical alignment of a road consists of straight segments (flat or inclined) connected by crest or sag vertical curves. The grade percent or grade difference are usually used to characterize the impact of vertical alignment on safety. A distinction is applied between a negative (or downhill) grade and positive (or uphill) grade. It is generally agreed that steep downhill grades increase vehicle acceleration and speed, and thus make a vehicle harder to control precisely, especially if it has a lot of inertia and increased handling difficulty, such as heavy goods vehicles (trucks). The situation can be particularly dangerous when a steep grade coincides with sharp horizontal curves, especially toward the bottom of the slope. Conversely, steep uphill grades induce additional deceleration, especially for heavy vehicles, which increases differentiation of speeds and crash risk. Thus, steep grades are often considered negatively in design, and most design manuals recommend avoiding or keeping to a minimum the use of steep slopes.

Concerning the estimation of safety effects of road design characteristics, best current knowledge on the topic is given in the form of crash modification factors (CMFs) or crash modification functions, which are based on the analyses of empirical data. A CMF indicates a relative change in crash frequency associated with a change in the design feature, that is, it represents the ratio of expected crashes with the new design element to crashes without it, assuming other road and traffic characteristics unchanged. CMFs less than 1.0 indicate that the design change is associated with safety improvement (fewer crashes).

The before–after study would be the most appropriate technique for quantifying the influence of design change on safety. However, due to the need for substantial crash counts to provide reliable estimates of CMFs and thus a consideration of many sites with a single change of the design feature, which is seldom possible in practice, most safety effects of road geometry characteristic are estimated by fitting multivariate regression models (cross-section study). Such a model predicts average crash frequency for sites with various values of the geometric feature of interest having controlled for traffic volume, segment length, and other road design characteristics.

It should be noted that the majority of current research findings with regard to safety impacts of horizontal and vertical road alignments belongs to rural (nonurban) roads and, particularly, two-lane roads, while similar results for other road types are not frequent. For example, the Highway Safety Manual in the United States (AASHTO, 2010) suggests no CMFs for horizontal or vertical curvature on rural multilane undivided and divided highways, and urban and suburban arterials.

Safety Impacts of Horizontal Curves

Typically, the crash risk in horizontal curves is greater than on straight sections. According to various estimates, the crash rate in curves is 1.5–4 times higher than in tangents, the severity of crashes in curves is high (25%–30% of all fatal crashes occur in curves), and a large proportion of crashes (60%) are single-vehicle off-road crashes (RSM, 2003). Increased crash rates are observed on horizontal curves due to the limited sight distance and the increased probability of skidding or rollover.

Curves also present road safety problems for specific types of road users. For example, motorcyclists are particularly at risk on curves, where acceleration and deceleration occur and the stability of the vehicle can be compromised. As reported (FEMA, 2012), riders are 15 times more likely to be killed than car occupants in collisions on curves (especially, when steel barriers without motorcycle protection devices are present on the roadsides). Trucks and other large vehicles are more susceptible to overturning at curves, because of their higher center of gravity. Research indicates that such overturning can occur at speeds only slightly greater than the design speed of the curve.

Curve Radius

The effect of curve radius has been extensively studied in many countries (Bonneson and Pratt, 2009; Elvik, 2013; Goldenbeld et al., 2017a). The results were consistent in showing that curves with shorter radii are associated with higher crash rates, but the results may be sensitive to other curve characteristics, for example, length of curve. In addition, the extent of the impact may change depending on the country (actually, the road design practice), road type, crash type, and other evaluation conditions. Across various models, the strongest increase in crash rates was observed for radii below 200 m. The tendency of the crash rate to increase with shorter curve radii was found not only for two-lane rural roads but also for multilane roads and access-controlled roads in rural and urban environments.

Fig. 1 presents examples of CMFs for horizontal curve radius in the United States, based on the widely used safety relationship for predicting total crashes on two-lane roads (Fig. 1A), and on the relationship between curve radius and injury (plus fatal) crash frequency on rural highways that was developed in Texas (Fig. 1B). The base condition for these CMFs is a tangent roadway. The horizontal curve radius CMF (CMF_{cr}) is estimated as:

In the case of a common US relationship for two-lane roads (AASHTO, 2010)

$$CMF_{cr} = \frac{1.55L_C + \frac{80.2}{R} - 0.012S}{1.55L_C} \quad [1]$$

in the case of rural highways in Texas (Bonneson and Pratt, 2009)

$$CMF_{cr} = 1.0 + 0.97(0.147V)^4 \frac{(1.47V)^2}{(32.2R^2)} \left(\frac{L_c}{L} \right) \quad [2]$$

where R —curve radius, feet; L_c —horizontal curve length, mile; L —segment length, mile; V —speed limit, mph; and S —the presence of spiral transitions ($S = 1$ if exist). Clearly, beside radius values, CMF_{cr} depends on other curve characteristics, for example, curve length, tangent length, and the presence of transitions. Fig. 1A indicates, for example, that shorter (sharper) curves are associated with higher crash numbers.

Fig. 2 depicts the summary crash modification function for a horizontal curve radius that was estimated by weighting the results from eight countries (Elvik, 2013). The function is:

$$\text{Relative crash rate} = 126.1658x^{-0.7099}, \quad [3]$$

where x is curve radius, in meters. The international average is limited to the upper radius of 1 km and is not suitable to account for other curve characteristics. However, it exhibits that the form of the relationship was similar in various studies, with a stronger risk of small radii.

For motorcycle crashes on curves, the impacts of small radii are even stronger. Prediction models (for motorcycle-to-barrier crashes, in the United States) showed that curves with radius of 820 ft. (250 m) or less increased the crash frequency rate by a factor

Figure 1 Examples of horizontal curve radius CMFs. (A) For crashes on two-lane highways, in the United States (cases with no spiral transitions). (B) For injury crashes on rural highways, in Texas (cases when curve length = segment length). of 10 and curves with radius less than 500 ft. (150 m)—by more than 40 times relative to curves with a radius in excess of 2800 ft. (over 800 m) (*Gabauer and Li, 2015*).

Transition Curves

Transition curves (or spirals) have regular radius changes, allowing for a gradual transfer between adjacent road segments with different curve radii. A gradually changing radius of the transition curve is supposed to be consistent with the natural path drivers follow as they steer into, or out of, a horizontal curve. Experience shows that if the transition from a tangent section to a circular curve is not achieved by a transition curve, there is greater risk of drivers making abrupt movements in order to negotiate the curve.

Fig. 3 shows examples of transition curve CMFs for two-lane highway curves with a radius of 500 ft. (150 m) or more (developed in Texas) (*Bonneson and Pratt, 2009*). The base condition for this CMF is that spiral transition curves are not present. The impact of

Figure 2 Summary crash modification functions for horizontal curve radius. Source: Produced based on [Elvik \(2013\)](#).

Figure 3 Examples of transition curve CMFs for two-lane highway curves (cases when curve length including spirals = segment length). Source: Produced based on [Bonneson and Pratt \(2009\)](#).

transition curves depends on horizontal curve length (L_c), segment length (L), and curve radius (R) as is given in the equation for spiral curve CMF (CMF_{sp}):

$$CMF_{sp} = 1 - \frac{0.012}{1.55L_c + \frac{80.2}{R}} \left(\frac{L_c}{L} \right) \quad [4]$$

The results indicate ([Fig. 3](#)) that safety benefits of transition curves are most notable for horizontal curves with larger radii but shorter in length (relatively sharp).

In general, safety impacts of the presence or absence of transition curves were not extensively examined in the literature ([Goldenbeld et al., 2017b](#)). Crash studies on the topic were mostly conducted in the United States; more recently, simulation and naturalistic driving studies, in various countries, explored driving behaviors while passing spiral transitions, in terms of speed, lateral acceleration, keeping desired vehicle trajectory, or similar indicators. The findings were not always consistent but sensitive to road conditions, for example, type of terrain, road width, length of spiral curves, etc. The findings generally suggest that the presence of transition curves is associated with better driving performance and lower crash rates, in flat terrain. However, some studies found negative safety effects of transition curves in rolling or mountainous area, that is, an increase in crashes.

In some studies, higher driving speeds were observed in the presence of transition curves; yet, the lateral acceleration rates were not affected in most cases. Most observation studies showed that spiral curves improved vehicle trajectories and/or resulted in less steering corrections. Hence, implementing transition curves is expected to have a positive effect on road safety (but dependent upon external factors). It should be noted that, overall, the safety effect of transition curves is not strong, indicating a crash change of a few percent only ([Fig. 3](#)).

Superelevation

Superelevation is provided on horizontal curves to offset some of the centrifugal force associated with curve driving. It reduces side friction demand and increases the margin of safety relative to vehicle slide out or rollover. It is assumed that if the superelevation provided on a curve is significantly less than the amount specified by road design guidelines, then the potential

Figure 4 Superelevation CMFs for total crashes. Source: Produced based on *American Association of State Highway and Transportation Officials (2010)*.

for a crash may increase. The amount of the superelevation deficiency can be measured as a difference between the superelevation rate that is specified in the design guideline and the actual superelevation of the curve. This measure is known as superelevation variance (SV, ft.ft.⁻¹), for example, in the US Highway Safety Manual, or superelevation deviation, in percent, in other sources.

The safety effects of deficient superelevation on horizontal curves were mainly reported in US studies; reduced crash rates in curves with improved superelevation were also found in Australia. Eq. (5) shows a commonly used relationship for superelevation CMFs on horizontal curves of rural two-lane highways (CMF_{sv}):

$$\text{CMF}_{\text{sv}} = \begin{cases} 1.00, & \text{for } \text{SV} < 0.01, \\ 1.00 + 6(\text{SV} - 0.01), & \text{for } 0.01 \leq \text{SV} < 0.2 \\ 1.06 + 3(\text{SV} - 0.02), & \text{for } \text{SV} \geq 0.2 \end{cases} \quad [5]$$

where SV is superelevation variance as defined earlier. The base condition for this CMF is a horizontal curve with superelevation deficiency within 0.01 ft.ft.⁻¹ related to the recommended design values.

Fig. 4 provides a visual presentation of the relationship between superelevation deviation and total (or injury) crashes. It shows that improving the superelevation may reduce the crash numbers on curves by 5%–15%.

Bendiness

Curves are considered to be a risk factor in the design of roads. However, the safety of a horizontal curve is affected not only by features internal to it (e.g., radius, superelevation, and the presence of transition that were discussed earlier) but also by features external to a particular curve that reflect the whole road design, for example, density of curves upstream, length of the connecting tangent sections, etc. The design of preceding road sections or general bendiness of the road may have a direct effect on the drivers' level of attention and expectations with regard to the forthcoming road alignment. Hence, they might influence driver behavior and curve approach speed, in particular, and the risk of crashes.

Road bendiness is examined for long road sections, routes, or network areas. In the literature, there are different ways for measuring bendiness such as:

- Absolute number of curves on the road, or curve frequency;
- Number of curves per kilometer, or curve density;
- Sum of deflection angles (or changes in direction, in degrees) per road kilometer, or curvature change rate; and
- Length of curves as a percentage of the road length.

Most research on the risk of curves focuses on individual curves, or on two-three subsequent curves, which are related to design consistency. The number of studies that tried to relate road bendiness or curve frequency to crashes, on longer road sections or on a network level, is not big.

Findings from the research studies on the topic are inconsistent. Some studies report a higher risk of crashes on roads with a higher degree of bendiness, others find no relation, while several more recent studies report a lower risk of crashes on road network units with a higher level of bendiness (e.g., Haynes et al., 2007; Jones et al., 2012). The authors of the latter studies hypothesized that such findings might be due to a higher driver attention on the network units with a higher degree of bendiness, which might cause drivers to drive slower and, thus, reduced the crash risk. In other words, higher bendiness may have a moderating effect on driving speeds and, hence, an inverse relation to crashes. However, such speed–bendiness relationship was not examined explicitly.

The reported studies considered spatial units of different size and on various road types, both rural and urban, which make a generalization of findings difficult. Some studies that reported a positive safety impact of bendiness did not consider traffic exposure, and most studies did not refer to safety measures applied on the roads that could affect the crash risk. In general, it seems that such a

macro-consideration of the road or network curvature raises additional demands on the range of possible confounding factors to be examined.

None of the reported studies examined a comprehensive list of possible traffic, road infrastructure, spatial and environmental factors, and, thus, it can be suggested that other factors might cause the change in crashes, where an increase in bendiness was measured, rather than those that were explicitly examined by the study. Hence, the results of available studies on the risk of bendiness do not yet represent a causal relationship with crashes, but merely reflect a relation observed, given the conditions that were taken into consideration.

Based on the current research findings, there is no clear expectation concerning the effect of road bendiness on crashes as well as with regard to the impact of the measure of reducing the number of road curves, on safety. Further research on the subject is needed with a particular focus on the definition of spatial research units and corresponding measures of bendiness, and on controlling for the effects of other possible confounding factors.

Safety Impacts of Vertical Alignment

Grade

Vertical grade can indirectly influence safety by influencing the speed of the traffic stream and speed differences between various types of vehicles. Uphill grades create significant speed differences between cars and trucks that may increase the frequency of lane changes and related crashes. Downhill grades accelerate the vehicle and place additional demands on vehicle braking and maneuverability. Steep downgrades are more dangerous for two-wheelers and, particularly, for bicycles. The design and safety literature distinguishes between constant grades and vertical curves.

According to the research findings in the United States, the presence of (positive or negative) constant grades, on two-lane rural highways, is associated with an increase in crashes. The summary estimates suggest that (AASHTO, 2010):

- For level grade, up to 3%, the CMF value is equal to 1 (no safety impact);
- For moderate terrain, with a grade between 3% and 6%, CMF is equal to 1.10, that is, a 10% increase in crashes is expected; and
- For steep terrain, with a grade of 6% or more, a 16% increase in crashes is expected.

The functional form for percent grade CMF (CMF_g) on a rural two-lane highway is given by:

$$CMF_g = 1.016^{abs(g)} \quad [6]$$

where $abs(g)$ is an absolute value of percent grade. It shows an increase in total crashes when vertical grade is higher than zero, yet a tangible change in crashes (of 5% or more) is expected when the grade value is over 3%.

A slightly different form of CMF for the relationship between grade and injury (plus fatal) crash frequency was developed for rural roads in Texas, enabling to separate the estimates for multilane versus two-lane roads, as follows:

$$CMF_g = e^{0.016g} \text{ for two-lane highways,} \quad [7]$$

$$CMF_g = e^{0.019g} \text{ for multilane highways,} \quad [8]$$

where g is an absolute value of percent grade (%). Fig. 5 presents both relationships and indicates that a higher grade is associated with higher crash frequencies and also that a slightly higher crash increase, under the same grade, is expected on multilane highways. As reported, similar estimates can be applied for evaluating safety effects of vertical curves.

Safety impacts of steep vertical grades were extensively explored in the international literature, including studies conducted in various states of the United States, China, South Korea, Italy, and other countries (Ziakopoulos et al., 2016). However, the risk factor

Figure 5 Examples of grade CMFs for injury crashes Source: Produced based on Bonneson and Pratt (2009).

of steep grade was typically not examined alone but appeared in conjunction with other road design features while the main purpose of the studies was to examine the safety performance of certain road types or sites. To quantify the effect of grade, frequently, a threshold approach was applied that categorized all grade values into “steep” and “not steep.” Some studies used a wider range of grade categories or continuous numeric approaches. The international results refer to various road types, including freeways, national roads, and all rural highways; some studies focused on intersections or freeway ramps only, while most studies conducted aggregate analyses of road sections.

The majority of findings were consistent indicating a detrimental effect of a steep grade on road safety, that is, increasing crash risk or injury severity associated with steep vertical grades. However, there have also been reported cases where no statistically significant effect was found for a steep grade or when a decrease in crash frequency was observed on some road segments for a corresponding one-unit increase in vertical grades.

Based on the majority of the research findings, reducing vertical grades is expected to have a mostly positive effect on road safety, although dedicated before–after studies on the topic are lacking in the literature.

Interactions Between Horizontal and Vertical Alignments

Most studies reported separate safety effects of horizontal curvature and percent grade, not accounting for the interactions between them. Such an approach assumes that the effect of a horizontal curve is the same whether it is located on a level roadway, a constant grade, or a vertical curve, or, similarly, that the effect of a constant grade is the same whether it is located on a tangent section or on a horizontal curve. Recently, several studies analyzed such interactions explicitly demonstrating the combined effects of both features.

A study based on a dataset of the State highways in Washington prepared a comprehensive classification of two-lane road segments into categories by their horizontal and vertical alignments and developed statistical models for predicting crashes, under various conditions (Bauer and Harwood, 2014). The models estimated main effects of traffic exposure, horizontal curves and vertical grades, and the interactions of both.

Table 1 presents examples of CMFs estimated for various combinations of horizontal and vertical alignments; in all cases, the base conditions belong to level tangent road sections. The results show clearly an increase in crash risk with shorter horizontal curve or higher vertical curvature, where the combined effects appear to be stronger than the values reported (previously) for separate features. Particular high crash risks were found for short horizontal curves combined with high straight grades and for steep sag

vertical curves combined with sharper horizontal curves. The results are in line with engineering judgment. The models provide useful tools for comparing safety performance of various road designs, based on the combined effects of road features. However, current findings are limited to rural two-lane highways, road segments only, and are not available for major intersection areas and for other road types. In addition, the impacts of other road features, for example, lane and shoulder width, superelevation, roadside conditions, etc., were not included yet in the combined analyses.

Evaluating Speeds

Horizontal and vertical road alignments are among the main road characteristics that impact on selecting travel speeds by drivers. It is generally assumed that, in their trip along the road, the driver relies on their experience of passing previous road segments. When abrupt changes appear in the road alignment, a conflict arises between the driver expectations and road conditions that may cause driver errors and lead to crashes. Conversely, when the road design is consistent and uniform, driver's expectations are satisfied leading to fewer driver errors and safer driving. This understanding brought to the creation of the road design consistency concept that was originated by German researchers several decades ago (Lamm et al., 1999). Operating speed is a commonly used parameter for estimating road design consistency. In the literature, a great number of models can be found for predicting operating speeds based on road geometry characteristics, while most of them were developed for driving on curves.

Design consistency is evaluated by considering speed differentials, for example, the differences between the operating speeds of consecutive road segments and between the operating and design speeds of the same road elements. A common approach suggests that good road design consistency is attained when both differences are below 10 km/h, a gap of 10–20 km/h can be accepted, whereas a difference over 20 km/h requires a redesign. Research studies provided empirical evidence supporting the above categories. It was found, for example, that the crash rate of curves from the last category was 6 times higher than that of the first group and 2 times higher than the crash rate of the second group (RSM, 2003).

As speed is considered today as a crucial factor both in crash occurrences and their consequences, road design consistency has much in common with road safety evaluations. Not surprisingly, many research studies dedicated to safety impacts of road geometry, on various road types, chose to focus the evaluation on speed indicators and their relationship with road design characteristics. Further conceptual developments lie in creating self-explaining (or self-enforcing) roads, whereby road design characteristics should deliver a clear message to drivers on the speeds appropriate for traveling on each road section. (An alternative approach is governing the actual speeds by GPS-based in-vehicle devices, e.g., intelligent speed adaptation.)

However, research findings on speed impacts of road design features are not straightforward with regard to expected safety impacts. For example, for rural two-lane roads in Israel, a moderating effect on travel speeds of the presence of horizontal curves and steep vertical grades was found, while straight and flat design was less suitable for reducing excessive speeds (Gitelman et al., 2016). Similarly, in a Canadian study, a reduced number of speeding vehicles was observed on urban roads with steep grades (Eluru et al., 2013). Such seemingly inverse effects on speed and crashes require further research for a better understanding of road geometry impacts on driver behaviors and crash occurrence.

Future Research

Evaluating safety impacts of horizontal and vertical road alignments, with consequent recommendations on safer road design, sets a great challenge for future research. Concerning the evaluation framework, the challenge relates to the high variability of crash numbers at individual sites, and the necessity to neutralize the external confounding factors. To ascertain the impacts of road geometry features, aggregated data for many road sites are required for the analyses, thus raising the need to control for other road design and traffic characteristics and their interactions. Ideally, it would be desirable to develop safety prediction models for various road types that consider the safety effects of a full range of design variables and their combinations and interactions. Such analyses will require more comprehensive databases than those currently available. In addition, further methodological developments are needed for macro-considerations of road curvature, for example, assessing safety impacts of road bendiness.

Additional research challenges lie in providing sufficient empirical findings for understanding the triangular relationship between road design features, driving speeds, and crashes, on various road types, aiming to support both safer road design and better speed management on the road network.

Introduction

In the early days of transportation, mechanical failures were common causes of transportation crashes. Advances in technology, mechanics, occupant protection, automation, and operational environments across all modes of transportation have led to steadily improving safety in terms of fewer crashes and injuries. With that said, in all modes of transportation, human error remains the leading cause of collision. This does not necessarily mean that the cure will be to change human behavior, which is very difficult, but rather the more effective cure is to design vehicles, roads, and operational environments with human limitations in mind.

In this article on human factors and transportation, we write about human factors mainly from the perspective of road users. This is our starting point because this is our research background. Also, and more importantly, in many cases, human factors considerations apply similarly across all transportation modes. Among others, visual acuity, perception of travel speed and closing velocity, fatigue, and alcohol effects have similar characteristics in operators in all modes. There are some major exceptions and these are noted. For example, the use of checklists is a very relevant issue in aviation, but not in other modes. Automation and its attendant problems are much further advanced in aviation than in other modes like marine, rail, and road, though automation in ground transportation is developing quickly.

We begin with a definition of human factors, followed by a brief comment on the contribution of human factors to crashes and incidents and the main issues across the modes.

Definition of Human Factors

“Human factors” is the scientific discipline concerned with understanding interactions among humans and other elements of a system in order to optimize human well-being and overall system performance. Human factors (also referred to as “ergonomics”) draws on knowledge from the human sciences—for example, psychology, physiology, kinesiology, and anthropometry—and applies it to engineering design. Human factors research examines the way people interact with tools (hardware and software), equipment and workplaces, and aims to make these interactions safer, healthier, and more efficient.

The discipline of human factors developed during the Second World War, when it became evident that engineering design that did not accommodate human limitations led to errors, injuries, and fatalities. Human factors research was first widely applied in the area of aviation, leading to the generally exemplary safety record we know today. Human factors research into road operator behavior emerged in earnest during the 1950s and 1960s. Research into operator behavior in the marine and rail environments began later and, some would say, has not yet received the same level of attention.

Causes of Incidents and Collisions

Transportation crashes and incidents are very rarely the result of a single cause. Rather, they occur as a result of failures in system safety; a system that includes, at minimum, vehicle operators, equipment and infrastructure, and the natural and organizational environments. With this in mind, a review of crash causes can provide insights into the ubiquity of human error and performance in transportation incidents and crashes.

One of the largest in-depth road transportation studies is the National Vehicle Crash Causation Study ([National Highway Traffic Safety Administration, 2008](#)). This US study considered a nationally representative sample of 5,471 crashes investigated during a 2½-year period. Each investigated crash involved at least one light passenger vehicle that was towed due to damage sustained in the collision. Data were collected on at least 600 potentially contributing elements to capture information related to the drivers, vehicles, roadways, and environment involved. The “critical reason” for crashes, defined as the last event in the crash causal chain, was assigned to a driver in over 94% of crashes. In those cases, about 41% of the critical reasons were recognition errors (e.g., inattention, internal and external distractions, inadequate surveillance), 33% were decision errors (e.g., driving too fast for conditions, misjudgment of others’ speed), 11% were performance errors (e.g., overcompensation, poor directional control), and 7% were nonperformance errors (e.g., the driver having fallen asleep). About 36% of the vehicles were turning or crossing at intersections just prior to the crashes—characterized as the critical pre-crash events.

With respect to pedestrian collisions, key factors are urban areas, not at intersections and dark conditions. In one U.S. study ([National Highway Traffic Safety Administration, 2018](#)), one-fifth of pedestrians killed were children aged 10–4 and one-fifth were aged 65 and older. An estimated 33% of fatal pedestrian crashes involved a pedestrian with a blood alcohol concentration (BAC) of 0.08 g/dL or higher. Bicycle collisions involve a similar pattern of factors. Pedestrians and bicyclists appeared to be at fault most of the time, with the largest percent of errors being failure to yield right-of-way for both groups (30.6% and 34.9% pedestrians and bicyclists, respectively ([National Highway Traffic Safety Administration, 2017, 2018](#))).

Within the domain of aviation safety, a generally accepted estimate of the percentage of crashes and incidents ascribed to the human element (most often, the pilot) is two-thirds ([Hitchcock et al., 2010](#)). Research ([Endsley, 2010](#)) on the causal factors underlying aviation crashes that involve a substantial human error component reveals that most can be attributed to problems involving a failure to correctly perceive some piece(s) of information. Reasons underlying the misperception include: that data were not available (12%); the data were difficult to detect or perceive (12%); the crew failed to monitor the data despite it being available (37%); the crew misperceived the available data (9%); or the crew forgot the data (11%).

While generally more forgiving of human error than other transport modes because of lower relative speeds and broader directional tolerance, the marine safety environment presents other challenges. Often, accident investigation is limited to identifying direct and contributing causal factors, whereas wider sociotechnical context that has given rise to causal mechanisms is left unexplained ([Puisa et al., 2018](#)). The American Bureau of Shipping ([McCafferty and Baker, 2006](#)) performed a meta-analysis and developed a common taxonomy of causes across international marine accident databases and found that “human error” was the dominant factor in 80%–85% of maritime accidents worldwide. Among all human error types classified, failures of situation awareness and situation assessment predominated, being a causal factor in about 45% (offshore operations) to 70% (ships) of the recorded collisions associated with human error.

Railroading is different from other transportation modes because it is almost entirely an industrial activity and therefore does not entail the same level of individual decision-making. Regardless, and similar to the other modes, it can be difficult to ascertain the contribution of human factors issues to railway collisions, as “human factors” tends to be seen as the “cause factor of last resort” behind other technical, equipment, or service system elements ([Hill, 2007](#)). Railways assign what are called “cause codes” to indicate the primary and secondary cause of an accident. Cause codes exist for human factors (118 codes), signal defects (21 codes), track defects (65 codes), mechanical/electrical problems (143 codes), and miscellaneous (42 codes). Interestingly, no codes are related to organizational and management issues such as shift scheduling (Federal Railroad Administration, 2019).

Visual Characteristics and Limitations

It is estimated that 90% of the information drivers use while driving is visual. With the advent of semiautonomous road vehicles, auditory warnings, and automated driving capabilities are growing more prevalent, mitigating some aspects of the safety risk. While other modes of transport are associated with varying levels of vehicle automation and operator warning systems, the speed with which recent developments in automation have evolved in road vehicles remains unrivaled. Further, while operator vision is important for all modes, the nature of the operating tasks across them differs significantly. While driving a road vehicle is an essentially constant visual task, the visual aspects of flying an aircraft, driving a train, or operating a vessel are less constant over time, so visual characteristics and limitations, while important, pose less safety risk.

There are many aspects of vision that are important in vehicle operation. The most familiar is visual acuity, the ability to resolve small details, such as text, at a distance. Acuity considerations affect the design of displays and controls within the vehicle, as well as externally, for example, road traffic signs. While visual acuity is the most well-known visual characteristic, there are numerous others that are as much if not equally important. These include:

- Peripheral vision, which facilitates an operator's ability to detect intersecting vehicles and objects moving in the periphery, such as pedestrians or other vehicles.
- Contrast sensitivity, which enables detection of slight differences in luminance or reflectance between an object and its background.
- Perception of closing velocity, or the ability to estimate the speed with which one is closing on another vehicle.
- Accommodation, or the ability of an operator's eye to change focus from nearby instruments inside the vehicle to objects outside the vehicle, and vice versa.
- Adaptation, or the eye's ability to adjust in terms of light sensitivity on entering and exiting lit environments, such as streetlight areas or tunnels.
- Color vision, or the eye's ability to detect color. Color vision is particularly important to the identification of display, signal and sign colors in the rail, aviation and marine modes, but less so in the road environment because of deliberate color choices and the consistent design of traffic signals.

The first four of these visual characteristics are described in more detail next.

Visual Acuity

Of all the visual abilities, one for which vehicle operators in all modes are tested is visual acuity, which relates to how well they can read text at a distance. Under ideal conditions, in daylight, with high contrast text (black text on a white background), a person with a normal visual acuity of 6/6 (20/20) can just resolve letters at 6.8 m for each centimeter of letter height.

Road vehicle driver licensing requirements for visual acuity are generally a corrected acuity of 6/12 (20/40), or the ability to read at 6 m (20 feet) what a person with normal visual acuity can read at 12 m (40 feet) distance. For text fonts used on highway guide signs, to encompass the visual acuity of more than 95% of young drivers, 75%–85% of older drivers, and night driving conditions, design driver acuity is 4.8 m/cm (40 feet/inch) of letter height.

In other modes of transport that are predominantly commercial in nature, operator licensing requirements stipulate more stringent visual acuity. For marine positions that involve watchkeeping duties, corrected distance acuity must be at least 6/12 (20/40) in each eye, and a minimum requirement for near visual acuity. In rail, individuals occupying positions that involve movement of equipment on the track are required to have corrected or uncorrected distance visual acuity of at least 6/9 (20/30) in the better eye and at least 6/15 (20/50) in the worse eye, and minimum corrected or uncorrected near acuity. In aviation, Canadian airline and commercial pilots must have a minimum corrected or uncorrected distance acuity of 6/9 (20/30) in each eye, and minimum near acuity (corrected or uncorrected).

Peripheral Vision

The peripheral field of view is large—approximately 55 degrees above the horizontal, 70 degrees below, and 90 degrees to the left and to the right (Guyton, 1969, p. 294). However, the acuity of peripheral vision is much poorer than that of foveal (central) vision. If visual acuity for objects seen in foveal vision, along the line of sight, is 6/6 (20/20) it will fall to about 6/18 (20/60) at 5 degrees away from the line of sight (Mandelbaum and Sloan, 1947; Olson, 1988). In other words, letters would need to be 3 times bigger when they are not looked at directly but are read at 5 degrees off the line of sight. The larger the angle, the poorer the visual acuity. For this reason, drivers and vehicle operators in other modes fixate directly on an object or area of interest and then search the visual scene by rapidly moving their eyes to the next point of interest and fixating there. It is during these brief fixations that we take in information and “see.”

Contrast Sensitivity

Contrast sensitivity is important to safety. It is the ability to detect small differences in light level (or luminance) between an object and its background. The lower the level of light and the smaller the target, the more contrast is required to detect and perceive an

object such as a curb, debris on the road, an approaching train at a level crossing, or a pedestrian. Similarly, limited contrast sensitivity will make it more difficult for pilots to detect (and avoid) other aircraft in their vicinity, for locomotive engineers to correctly identify railway signals, and for mariners to detect other vessels or hazards in the water.

Good visual acuity does not necessarily imply good contrast sensitivity. For operators with 6/6 (20/20) visual acuity, the distance at which nonreflectorized objects are detected under full dark conditions can vary by a factor of 5 to 1. Therefore if using low beam headlights at night, drivers can get very close to a low contrast target before detecting it. Experimental studies show that even alerted drivers can come as close as 9 m before detecting a pedestrian in dark clothing standing on the side of the road (Olson and Sivak, 1983). Compounding the safety risk, pedestrians are unaware of how poorly drivers see them, over-estimating by a factor of two the distance at which they are seen (Allen et al., 1970).

Perception of Closing Velocity

Operator ability to estimate one's closing speed to another vehicle or object in the environment is generally very poor. One of the main cues for the road vehicle driver in determining the rapidity with which one is closing on another vehicle is the apparent change in the angle created at the eye by the rear end of the vehicle ahead, or by the front end of an oncoming vehicle. The determination of closing speed is difficult because, at a distance, the apparent size of the other vehicle is small. As the driver approaches, the size grows gradually at first and then faster and faster. This change in size is a nonlinear cue, making the driver's judgment of the rate of closing velocity very difficult. Studies suggest that alerted drivers in experimental situations do not even **begin** to be able to distinguish rapid from slow separation until the change in angle is, on average, 0.003 radians per second (Olson and Farber, 2003). Until this threshold is reached, all the driver perceives is that the gap is closing, something that happens regularly in traffic and does not precipitate emergency action. Fig. 1 shows how nonlinear the change in image size is as an object approaches closer and closer (Olson, 1996). It is this nonlinearity that greatly contributes to the difficulty observers have in making accurate estimates of other vehicles' speed.

Due to the poor ability of drivers to assess closing speed, they are at risk of several crash scenarios when in the presence of insufficient cues: rear-end crashes when they catch up to stopped or slowing vehicles, accepting too-small gaps when overtaking (Farber et al., 1967), or accepting too-small gaps when turning left across opposing traffic.

There are other challenges to the perception of closing velocity in modes of transportation other than road. For pilots, who operate in three dimensions, the basic method of visual collision avoidance follows the "see-and-avoid" principle, which is based on active scanning and a pilot's ability to detect conflicting aircraft and take appropriate measures to avoid them. This ability is affected by many factors, including physiological limitations of human visual and motor-response systems, obstructions to field of view, aircraft conspicuity, pilot scanning techniques, workload, and alerting to the presence of other aircraft. The effective practice of see-and-avoid can be influenced by limitations in what can be seen and by other activities, such as in-flight monitoring of instruments, radio communications, flight training exercises and interactions with an instructor, and navigation or conduct of simulated instrument approaches. A pilot's full attention may thus be diverted from active scanning for traffic. Research (FAA, 2016) has determined that, for pilots to have sufficient opportunity to avoid a collision, they must be able to detect a conflicting aircraft a minimum of 12.5 seconds prior to the time of impact. This delay in reaction time can and does vary depending on pilot experience, and is likely to exceed 12.5 seconds, regardless of a pilot's experience or training.

Figure 1 The nonlinear relationship between viewing distance and image size. Source: Thomas Smahel adapted from Olson, 1996.

Cognitive Characteristics and Limitations

Information Processing and Attention

Human attention and abilities in information processing are limited. These limitations can create difficulties because operating any vehicle requires the division of attention between control tasks (e.g., staying in the lane, following a planned course), guidance tasks (e.g., merging with other vehicles, avoiding other vessels or aircraft), and navigational tasks (e.g., looking for street name signs, plotting an upcoming course change). While attention can be switched rapidly from one information source to another, humans attend well to only one source at a time. Furthermore, humans can extract only a small proportion of the available information from the forward scene. It has been estimated that, out of over 1 billion bits per second of information directed at the sensory system, roughly 16 bits per second are consciously recognized (the answer to a single yes/no question provides 1 bit of information) (Grandjean, 1988). In short, the human information processing system is essentially a single channel system with limited capacity (Grandjean, 1988; Kantowitz and Sorkin, 1983). Given these limitations in information processing, it is not surprising that vehicle operators are more likely to make errors when they are faced with high demands from more than one information source (e.g., attending to a navigation task while simultaneously changing lanes), because of information overload. They also rely on design being as expected—when expectations are violated (e.g. where there is a left hand exit from a freeway, or a white light on the rear of the vehicle ahead), drivers are more likely to make errors and respond slowly.

Expectancy

Information processing load on operators is reduced by designing operational environments (e.g., roadway, cockpit, bridge) in a predictable manner, according to operator expectations. Expectation is a powerful determinant of accuracy and reaction time. To take a very simple everyday example, as we enter a dark room that we have never entered before, we expect the light switch to be about shoulder height and near the edge of the door. We also expect to move it up to turn it on. If it is placed as expected, and operates as expected, we can locate it and turn the light on quickly. If it is not placed as expected—say at waist height, and operates differently than expected, for example, it moves laterally instead of vertically, our response time will be considerably longer. Similarly, drivers will respond slowly and inaccurately when roads and traffic control devices are not designed according to their expectations. This is a central tenet of the “positive guidance” approach to highway design. This approach, based on a combination of human factors and traffic engineering, was developed in the 1970s by two psychologists, Alexander and Lunenfeld, and elaborated on in a series of documents published by the US Federal Highway Administration (Alexander and Lunenfeld, 1975).

When drivers are surprised because their expectations are violated, slowed responses and errors occur. An example of such a violation of expectations is the use of left side exits on freeways. It has been known since the 1960s that left exits are associated with over twice the crash rate of right exits. Similarly, it has been known for many years that crash rates are higher on a sharp curve that occurs after a series of gentler curves than on a sharp curve that is characteristic of the other curves on that roadway.

Expectations also affect vehicle operator performance in the other modes of transportation. For example, pilots operate in a complex environment with multiple sources and types of information to monitor. To operate an aircraft effectively, pilots must pay attention to the most meaningful information needed for the task they are performing at that time. To help them cope with the large amount of information in the environment that is available to the senses at any given time, humans have developed expectation ‘biases’ that can facilitate the processing of information. These normal biases, however, have an unintended consequence: not all of the—potentially critical—elements in the flight environment will be attended to, which can lead to poor decisions and increased accident risk. For example, when the amount of available information about a situation is limited, pilots (and other vehicle operators) may tend to rely heavily on the first piece of information that was available to them to inform subsequent situation assessments. This is known as “anchoring bias,” and can make unfolding situation assessment less accurate than otherwise. Similarly, having only limited information about a situation can increase a pilot’s tendency to look for evidence that confirms or matches one’s current assessment or decision, a phenomenon known as “confirmation bias.” These biases can make it less likely for a pilot or other vehicle operator to reassess their initial assessment and update it with new information, or lead them to hand-pick information that supports their current decision, while dismissing information that is opposite to what is expected (Tversky and Kahneman, 1982). The danger in both circumstances is that alternative outcomes will not be given an appropriate level of consideration when deciding on the best possible course of action.

Research and past accident investigations have demonstrated that, once a plan is made and committed to, it becomes increasingly difficult for an individual to recognize stimuli or conditions in the environment as necessitating a change to the plan (Orasanu et al., 1998). “Plan continuation bias” is the “deep-rooted tendency of individuals to continue their original plan of action even when changing circumstances require a new plan” (Berman and Dismukes, 2006). If a reason to change the plan is to be recognized and acted upon in a timely manner, a condition or stimulus needs to be perceived as sufficiently salient to require immediate action. When plan continuation bias interferes with a pilot’s ability to detect important cues, or if the pilot fails to recognize the implications of those cues, nonoptimal decisions that can compromise safety become more likely.

In the marine domain, bridge controls and consoles that do not operate according to a bridge crew’s expectations can lead to errors and unwanted situations. As integrated bridge and automated control systems become more common on vessels, it is important to design interfaces that operate as expected by their human operators, while at the same time providing concise and accurate feedback regarding system status.

In rail, the expectations of locomotive crews make up an integral component of train operations. For many years, the railway industry in Canada has relied on crew compliance with wayside track signals that provide them with a series of signal indications requiring actions relative to the signals displayed. In this context, train crews are expected to react to the progression of wayside signal indications. The principle of progression for a series of signals is strongly instilled in experienced train crews, as they are trained and expected to react to wayside signal indications as presented along the route. In fact, however, rail traffic controllers will minimize the amount of information passed on to operating crews to reduce the risk of anticipation that can result in crew expectation bias related to the signals ahead.

Driver Visual Search

Eye movement studies illustrate the briefness of fixations and the demanding nature of driving (Rockwell, 1988). Visual demands on pilots, mariners and rail engineers are very different from those on drivers because they are less constant over time. Further, unlike that of a road vehicle, train control does not involve a lateral element. And flying is undertaken in three, as opposed to two, dimensions, meaning visual search will be more varied than that in the other modes.

For drivers, visual search is generally concentrated at or below the horizon, and, for right hand driving jurisdictions, approximately 5 degrees to the right of the focus of expansion (the point in the distance where parallel lines appear to merge). Drivers look ahead of their vehicles by 2–3 seconds to monitor changes in the road path, and deliberately fixate particular areas, depending on the driving task. For example, they will look towards the right when searching for traffic signs, as that is where most of them are found. In contrast, pilots need not focus on the path ahead except in very specific circumstances, such as during takeoff and landing. Similarly, mariners need to focus directly ahead during berthing maneuvers and when navigating narrow passages.

In terms of eye movements, drivers make three fixations a second on average (Mourant and Rockwell, 1970) and fixations last for between 1/10 second up to about 2 seconds (Rockwell, 1988). At speed limits of 50–100 km/h, on the order of 5–0 m would be covered during an average glance duration. This means that the number of eye fixations that can be made, and the number of objects that can be identified as a driver drives through a particular area, is very limited. Because of the importance of visual search for road vehicle lane-keeping and directional control, drivers are loath to go for more than 2 seconds without getting some information from the roadway (Rockwell, 1988).

Besides looking in particular areas for information (what is known as “top-down processing”), drivers and other vehicle operators rely on their peripheral vision to detect targets of interest to be fixated (what is known as “bottom-up processing”). The targets most likely to be detected in peripheral vision—what is also known as an object’s “conspicuity”—are those that are large, moving, have good contrast with their background, and are consciously being searched for. The further a target (e.g., a pedestrian, intersecting vehicle or oncoming aircraft) is off the line of sight, the longer it will take for the driver or other vehicle operator to detect and the more likely it is to be missed.

Useful Field of View (UFOV)

Although, as noted earlier, the peripheral field of view is large, the portion of that field of view which is used while driving or operating any kind of transport vehicle is much more limited. Useful field of view (UFOV) is defined as “the total visual field in which useful information can be acquired in a single fixation.” A laboratory study (Ball et al. 1988) examined the effect of central task demand, number of distractors, and age on participants’ ability to locate a target stimulus (a cartoon of a human face) at 10, 20 or 30 degrees off the forward line of sight during a single fixation (Ball et al. 1988). The greater the central demand (e.g., indicating whether the central human face was smiling or frowning versus looking at a static central fixation point), the greater the number of distractors and the greater the eccentricity, the more frequently targets were missed. Error rates for 30 degrees were 25% or higher depending on the number of distractors that were present and the difficulty of the central task. Applying these findings to the issue in question, the more demanding the operating task and the further the target (e.g., a pedestrian, an oncoming aircraft) is off the forward line of sight, the more likely it will be missed.

An on-road driving study examined what properties, and driving circumstances, affected target detection (Cole and Hughes, 1984). One group of participants was asked to report whatever objects they noticed as they drove. The other group was asked to search for and report disc targets that had been set up by the experimenters along the roadway. The disc targets were considerably more likely to be identified when participants were asked to search for them specifically (approximately 40% of those in a shopping area were identified, rising to approximately 80% of those in a residential area). When participants merely reported what attracted their attention and were not asked to search for the disc targets, they only noticed about 6% of them in the shopping area and about 40% of them in the residential area. The more intentional the drivers were in looking for particular targets, the more likely they were to detect them. Nonetheless, even though the participants searched for the targets, many of them were missed, especially in visually cluttered urban areas. Objects that were not being deliberately searched for tended to be first noticed when they were relatively small in angular size (less than 1 degree) and at small angular eccentricities (less than 10 degrees off the driver’s line of sight).

A second on-road study exploring UFOV (Cohen, 1987) measured driver perception-reaction time to stimulus lights placed at various angles away from the forward line of sight, while drivers drove in various environments, on highway, rural road and urban streets. Drivers were required to respond to the onset of a stimulus light by touching a metal ring mounted on the steering wheel. If a light was not responded to within four seconds, it was turned off and counted as a miss. For participants, who were well-experienced police car drivers, on urban streets, 27% of the targets were missed when the angle between the target and the driver’s line of sight was

15 degrees. When the angle increased to 25 degrees, about 50% of targets were missed. Perception-reaction time for targets 15 degrees off the line of sight averaged 1.5 seconds—25%–50% longer than for targets seen up to 5 degrees off the line of sight. The author noted that perception-reaction times to more complex events than a red light illuminating for nonalerted drivers, are certain to be considerably longer than the measured values (Cohen, 1987).

Targets that are highly contrasted with the background against which they are seen (Bullough and Rea, 2000), or are moving, are more likely to be seen further off the line of sight in peripheral vision than stimuli that have poor contrast with the background or are static (Boff et al., 1986). Thus, the extent of the UFOV will be dependent in part on the conspicuity of the visual stimulus. The detectability of stimuli also depends on whether the observer is actively searching for them or not. An on-road driving study found that, during a merging task, the average peripheral detection angle for passing vehicles was 87 degrees from forward, considerably greater than the 10 degrees at which objects not being actively searched for were noticed in the study described above.

Stressors

Distraction

Operating any kind of vehicle is a complex task, involving the coordination and execution of various cognitive, physical, sensory, and psychomotor skills (Young and Regan, 2007). Despite this complexity, it is common to see road vehicle drivers engaging in other ‘secondary’ activities ranging from the seemingly benign (e.g., talking to a passenger) to the potentially hazardous (e.g., eating a bowl of cereal) (Regan et al., 2009).

Driver distraction is “the diversion of attention away from activities critical for safe driving towards a competing activity” (Lee et al., 2009). It can impair the ability to detect, recognize and respond to hazards. Distraction is typically categorized into types, depending on the source. *Visual* distraction refers to a driver neglecting to look at the road scene and instead focusing his or her visual attention on another target, such as a cell phone’s keypad or touchscreen, or on a child in the rear seat. *Physical* (or manual) distraction occurs when drivers remove one or both hands from the steering wheel to physically manipulate an object, for example, a lid on a coffee cup or handheld cell phone or music player. *Cognitive* distraction occurs when a driver’s attention is withdrawn from driving and applied instead to a nondriving related activity, such as a cell phone conversation (Strayer et al., 2013) or simply being “lost in thought” (Martens and Brouwer, 2013). Road users other than drivers, such as cyclists (Stelling and Hagenzieker, 2012) and pedestrians (Nasar et al., 2008), can also experience distraction, as can pilots, locomotive engineers and mariners.

Driver distraction is a primary contributing factor in motor vehicle crashes, and is a significant safety concern worldwide (World Health Organization (WHO), 2011). Research conducted under “naturalistic” conditions, where everyday drivers operate their own vehicles while a range of video and vehicle performance data is recorded and later analyzed, has consistently found that driver eye glances away from the forward visual scene are, not surprisingly, associated with crashes and near-crash events (Fitch et al., 2013; Klauer et al., 2006). A two-second glance away from the forward view doubles the risk of a crash.

Passengers can also be a source of cognitive (and visual) distraction (Stutts et al., 2003) for all ages of driver, and rear-seated child passengers can be particularly distracting to parent drivers (Koppel et al., 2011). Pets riding in vehicles can also lead to distraction. A recent anonymous, online, self-report survey from the United Kingdom of over 482 respondents found “interaction with pets” to be the third most common distracting behavior resulting in an accident, with 1.7% of respondents reporting having had an accident while driving with pets (Lansdown, 2012).

Risks from 50 different distracting activities were examined in an extensive naturalistic driving study involving over 3000 drivers, whose vehicles were instrumented over a one to two year period (Victo et al., 2015). Distraction involving “portable electronics visual-manual devices” had the highest odds ratio for the risk of a crash, with texting having the highest odds ratio of 5.6.

Distraction can similarly impair an operator’s performance in other modes of transportation. For example, a pilot’s ability to attend to critical stimuli within their environment will be impaired if they are distracted or inattentive, and will result in impaired situation awareness (Endsley, 1995). In light of this risk, many commercial air operators have standard operating procedures in place to limit the potential for pilot distraction. These “sterile flight deck” rules are intended to ensure that pilots experience a minimum of distraction during critical phases of flight, such as takeoff and landing, and that critical tasks are not interrupted. More specifically, the rules warn pilots to avoid unnecessary communication other than in an emergency or to communicate information essential to the safety of passengers or aircraft.

The rail mode in Canada restricts the use of communication devices to matters pertaining to railway operations, and cellular telephones are not to be used when normal railway radio communications are available (Transport Canada, 2018). The use of personal entertainment devices is also prohibited. There are presently no Canadian regulations with respect to the use of personal communication devices in the marine mode. In lieu of specific regulations, however, some pilotage associations have general requirements for marine pilots that they must apply their full attention to the task of piloting, and that any irrelevant activity that can distract from the piloting task is incompatible with this obligation.

Fatigue

Fatigue (or sleepiness) is prevalent among operators in every mode of transport, but particularly in commercial transportation operations. A US study by the National Transportation Safety Board (NTSB) of 107 single-vehicle nighttime truck crashes found that

58% included fatigue as a probable cause. The most critical factors in predicting which nighttime crashes were fatigue-related were: the duration of the driver's most recent sleep period, the amount of sleep in the past 24 hours, and split sleep patterns (due to the use of sleeper berths). The truck drivers in fatigue-related crashes were found to have obtained 2.5 hours less sleep in the last sleep period than the drivers involved in nonfatigue-related crashes. A major study conclusion was that "driving at night with a sleep deficit is far more critical in terms of predicting fatigue-related crashes than simply nighttime driving" (NTSB, 1995).

On-road, a 2007 survey found that 15% of Canadian respondents admitted that they had fallen asleep while driving during the past year (Vanlaar et al., 2008).

Fatigue can easily lead to impaired hazard detection, increased perception reaction time, or even a complete failure to react. Ultimately, it can lead to crashes, with about 20% of fatal traffic collisions in Canada involving driver fatigue (Transport Canada, 2011).

Whether an operator is fatigued is mainly dependent on the body's circadian (daily) rhythm, hours of continuous wakefulness, the quality and duration of recent and chronic sleep, and medical conditions that impair one's ability to obtain adequate restorative sleep, such as obstructive sleep apnea (OSA). The monotony of the operating task itself can also exacerbate sleepiness.

Fatigue and its counterpart, alertness, are determined by the body's circadian rhythm—a daily variation of various physiological functions such as sleep, body temperature, adrenalin production and many others. The circadian rhythm physiologically gears the body for action during the day and for sleep at night. Body temperature, for example, rises slowly throughout the day, peaking at about 8 pm. It then falls rapidly to reach a low point at approximately 3:00 a.m. (Grandjean, 1982). Along with fluctuations in body functions go fluctuations in physical capacity and mental alertness that also have a 24-hour cycle. Mental abilities peak during the daylight hours, and are poorest at night, particularly around 3:00 a.m. There is a secondary low point in the afternoon, known as the "post-lunch dip." Various studies from a number of countries show a very large increase in road accident crash risk by time of day, with the early morning hours having as much as 25 times higher crash risk than other hours of the day (Horne and Reyner, 1995). Night-shift workers are particularly vulnerable to motor vehicle crashes. A survey of 957 emergency medicine residents found that crash risk on the drive home from work was significantly higher, by a factor of six, after working night shifts than after day shifts. Further, the likelihood of having a crash increased significantly with the number of night shifts that had been worked in a sequence (Steele et al., 1999).

Fatigue can be caused by staying awake for a long period of time. In total, 22 hours of continuous wakefulness is commonly considered the point at which fatigue causes almost all aspects of human performance to decline and for "micro-sleeps" to begin (Beaumont et al., 2001). Fatigue may result from fewer hours of continuous wakefulness if these hours occur at night, rather than during the day, even for regular night workers.

Task monotony can also contribute to an operator's level of fatigue. People who experience monotonous stimuli are more likely to fall asleep than those who simply sit quietly in a dark room (Oswald, 1966). The monotony of driving on a familiar route or on a monotonous highway can contribute to fatigue and to falling asleep. Rail, marine, and long haul flights are also well recognized as soporific (sleep-inducing) environments. In aviation, flight crews can cross several time zones during a work period and face the added negative effects of circadian de-synchronization, or "jet lag." When these factors are considered in the context of the 24 hours a day/7 days a week reality of the commercial transportation industries, it is easy to see how and why fatigue is such a critical issue that needs to be addressed. In fact, the Transportation Safety Board of Canada (TSB)'s 2018 Watchlist includes "fatigue management in rail, marine and air transportation" as one of 7 key safety issues that need to be addressed to make Canada's transportation system even safer.

Finally, certain medical conditions can limit the quality and quantity of sleep that a vehicle operator obtains, which can contribute to fatigue. For example, a study of drivers who had been implicated in "falling-asleep-at-the-wheel" crashes found that many showed signs of OSA (Arbus et al., 1991), a medical condition and sleep disorder characterized by episodes when breathing ceases during sleep, resulting in frequent awakenings and chronic daytime sleepiness. Of all drivers evaluated, 62% had some form of sleep disorder.

The prevalence of OSA in the general public has been estimated to be 4% in men and 2% in women (Young et al., 1993). Some estimates indicate a higher prevalence for middle-aged men, especially if they are overweight, perhaps as high as 10% for men between the ages of 40 and 60 (Bearpark et al., 1990). It is more common in people who snore (AASM, 2001), and is reliably linked to large neck size (Chung and Elsaid, 2009), obesity (Dagan et al., 2006), and cardiovascular disease, including hypertension (Lurie, 2011).

OSA is associated with increased risk of motor vehicle crashes, which may result from lapses of consciousness, slow or inappropriate reactions, or from impaired judgment (Teran-Santos et al. 1999). OSA sufferers have a 2–10 fold increased risk of having a driving accident compared to people without OSA depending on the study cited (Ayas et al., 2006, 2014; Ellen et al., 2006; Karimi et al., 2013; Philip and Akerstedt, 2006), and are more than 6 times as likely as nonsufferers to have a traffic accident requiring hospitalization (Teran-Santos et al. 1999).

As with motor vehicle drivers, operators in other transportation modes are also at risk, though some more than others. In aviation, the US Federal Aviation Administration issued medical guidance relating to OSA in 2015 because of a 2008 incident investigated by the US NTSB. In that incident, the crew flew past their destination airport in Hawaii after both crew members fell asleep during the flight. The NTSB determined that the probable cause was the captain and first officer inadvertently falling asleep during the cruise phase of flight. Contributing to the incident was the captain's undiagnosed OSA. The NTSB concluded that efforts to identify and treat OSA in commercial pilots were needed to improve the safety of the traveling public, and recommended a

program to identify pilots who were at high risk for OSA and require that those pilots provide evidence of treatment before being granted unrestricted medical certification.

Medical guidelines in the rail mode provide a practical process by which all operating employees can be screened for OSA and subsequently diagnosed and managed appropriately. According to the guidelines, individuals with severe OSA cannot be considered fit to work until written confirmation and appropriate data have been provided by the treating physician indicating that effective treatment has been achieved and that the individual is compliant with therapy.

Medical Conditions

There are certain other medical issues that can impair human performance and vehicle operation. As discussed above, OSA is an important and common one. Based on two European studies, other 'high' risk conditions for motor vehicle crashes include alcoholism, mental disorders, neurological disorders, diabetes, and conditions resulting in mobility disorders (Sagberg, 2006; Vaa, 2003). The Ontario Ministry of Transportation has recently implemented screening for neurological disorders, such as dementia, that can impair driving performance as part of the age 80 years and up assessments. Finally, pain from chronic conditions like arthritis, and acute injuries and recent surgery can limit one's ability to operate a vehicle by limiting one's range of motion and the effectiveness of visually scanning the environment. Mental health conditions like depression can have secondary effects on performance by disrupting, for example, sleep. They can also have indirect secondary effects through medication to control symptoms like anxiety, which may have corollary negative psychoactive effects on for instance psychomotor (e.g., hand-eye coordination) control.

Inexperience

Compared to older, more experienced drivers, young novice motor vehicle drivers (i.e., those under the age of 21) are at an increased risk of having an accident, especially in the first few months of licensure (Cooper et al., 2005; IIHS, 2012; Lam et al., 2003). On average, young, novice drivers are much slower to detect hazards, and identify fewer hazards, than experienced drivers (Lee, 2007). This is especially true for hazards that are located further away, which implies more limited visual search strategies for novices.

Similarly, motorcycle riders' visual scanning patterns change with increasing riding experience, with novice riders demonstrating narrower visual scanning patterns compared to experienced riders (Hosking et al., 2010). The hazard perception ability of motorcyclists improves with experience (Liu et al., 2009), and car driving experience also appears to have positive effects in terms of hazard perception ability in motorcycle riders.

The presence and number of peer-aged passengers further increases the crash risk of young novice drivers. There is an exponential, stepwise relationship between the number of passengers and risk of having an accident (Chen et al., 2000; Tefft et al., 2012); compared to no passengers, having one passenger younger than age 21 leads to a 44% increased risk of being killed in a crash; having two passengers younger than 21, results in a doubling of risk; and having 3 or more passengers younger than 21, results in a quadrupling of a young driver's risk of death in a crash. The increased risk from carrying passengers is particularly strong when the passenger(s) is/are male (Simons-Morton et al., 2005). The mechanism for young novice drivers being at increased risk of collision when carrying peer-aged passengers likely involves the verbal interaction among them (Lam et al. 2003; White and Caird, 2010).

Age

As drivers age, many aspects of vision change, including visual acuity, contrast sensitivity, sensitivity to glare, dark adaptation, and field of view (Dewar and Olson, 2007). As a result of changes in sensitivity to contrast, older drivers have shorter seeing distances at night. For example, Sivak et al. (1981) matched groups of younger (age 18–30) and older (age 60–75) subjects in terms of daytime acuity, and found that the older subjects could read highway signs at night at an average of only about two-thirds the distance as compared to younger subjects (Sivak et al., 1981; Olson and Farber, 2003). Many aspects of cognition also change with age. Older drivers are unable to divide attention as easily and are more easily distracted from a primary task, such as driving. The UFOV test shows a decline in performance with age, suggesting greater constriction of the field of view with increasing age. Older drivers with UFOV impairment are more likely to have a crash (Owsley et al., 1991). Finally, with age comes increased likelihood of medical conditions, the most concerning of which are cognitive impairments, including dementia, which can increase crash risk by a factor of three (Diller et al., 1999).

Compared to middle-aged drivers (those aged 45–59), on a per-kilometer-driven basis, those in their late 60s have a 30% greater chance of being involved in an accident. Those aged 70–74 years are 90% more likely (Hildebrand, 2012). The risk is even higher for aging commercial truck drivers, with those drivers over the age of 70 being over 7 times more likely to experience a collision than those aged 41–50 years. This disparity among commercial drivers is likely due to higher levels of driver workload than general driving, increased complexity of the driving task and the inability for commercial drivers to "self-regulate"—voluntarily reduce their exposure to risks by making fewer, or shorter, trips.

The increase in accident risk associated with aging has led to some jurisdictions in Canada enacting mandatory retirement for some commercial (e.g., school bus) drivers, usually at the age of 65. In recent years, however, all provinces and territories repealed their mandatory retirement laws due to human rights issues. However, exceptions can be granted that permit mandatory retirement at a given age in cases where a *bona fide* occupational requirement can be demonstrated, such as for occupations that are considered

to be safety critical. For example, in Ontario in 1992, mandatory retirement of school bus drivers at age 65 was upheld because expert medical evidence indicated that, as a group, those over 65 are more likely to have crashes than younger drivers, and because it is impossible to test individually to determine who is likely to pose risks to others.

Canadian commercial aviation operators have been able to use the *bona fide* requirements to implement mandatory retirement ages for pilots. For example, some pilot collective agreements stipulate 60 as the compulsory age of retirement. However, legal challenges to the requirements have been many. Although pilots older than 60 are permitted to fly, international rules require them to be scheduled with a co-pilot who is younger. There is no mandatory retirement age for locomotive engineers in Canada. However, according to the [Seafarers International Union \(2008\)](#), as of 2008, the mandatory retirement age for seafarers was 70½.

Alcohol and Drug Effects

Alcohol

Alcohol effects on motor vehicle driving have been studied extensively, beginning as early as 1904 ([Moskowitz, 2007](#)). Alcohol consumption has been shown to impair visual search, the ability to divide attention, and information processing ([Moskowitz and Robinson, 1988](#)). Alcohol affects driving even at very low BAC levels and the effects are dose-related. With respect to driving tasks, alcohol is associated with impaired control of lane position, faster speeds, and slowed response time to subsidiary tasks ([Smiley, 1999](#)). As BAC level increases, more aspects of behavior are affected and are affected more strongly.

In Canada, it is a criminal offence to operate road, railway, or boating equipment or be in care and control of railway equipment while impaired by alcohol with a blood alcohol level of 80 milligrams of alcohol in 100 milliliters of blood (0.08%). There are lower (e.g., 0.05%) BAC limits in many provinces for which exceeding them is considered an administrative offence. This can result in, for example, temporary suspension of one's driver's license.

The International Maritime Organization recommends that countries implement national legislation prescribing a maximum of 0.08% BAC during watchkeeping duty as a minimum safety standard. International marine regulations issued under the STCW (Standards of Training, Certification and Watchkeeping for Seafarers) in 2011 include mandatory limits for alcohol consumption of not greater than 0.05% BAC or 0.25 mg/l alcohol in the breath, although individual flag states may choose to apply stricter limits.

Marijuana

Generally the effects of consuming marijuana are that it: "... impairs driving behavior". However, this impairment is mitigated in that subjects under marijuana treatment appear to perceive that they are indeed impaired. Where they can compensate, they do, for example by not overtaking, by slowing down and by focusing their attention when they know a response will be required. Such compensation is not possible, however, where events are unexpected or where continuous attention is required" ([Smiley, 1999](#)). A meta-analysis of experimental studies on the impairment of driving-relevant skills by alcohol or cannabis shows that a tetrahydrocannabinol (THC) concentration in serum of 7–10 ng/ml is correlated with an impairment comparable to that caused by a BAC of 0.05% ([Grotenhermen et al., 2007](#)). Effects have been shown to last a few hours, however more research is needed on this issue as a single study in aviation found effects still present 24 hours after dosing. A difficult problem arises with medical marijuana because the active ingredient in marijuana can stay in the body for several hours or longer, long after there is any effect on performance.

New Developments in Human Factors and Transportation

Automation

The role of operators of automated systems is to supervise the system, monitor its performance and, when required, intervene. The concept of "trust in automation" ([Sheridan, 1980](#); [Sheridan and Hennessy, 1984](#); [Sheridan et al., 1983](#)) describes individual differences in the use of, and reliance upon, automated systems. Trust evolves over time as one analyzes, compares and interprets the capabilities of a system ([Lee and See, 2004](#)). As with people, a pilot's trust—or distrust—of an automated system will develop with repeated exposure, and will be less likely to change as experience with the system increases. The extent that an individual will allow an automated system to perform and manage functions that could also be performed by the individual will depend on the amount of trust felt towards it.

If understanding of automation is poor, operators' expectations about how and when automation will intervene will tend to be inaccurate, and may be unreasonably high. The more trust an operator feels towards an automated system, the less often they will monitor it ([Muir and Moray, 1996](#)) and the "raw" information sources that it uses ([Parasuraman et al., 2008](#)), a situation that may lead to reduced vigilance and alertness, and less accurate situational awareness ([Parasuraman and Riley, 1997](#)). "Calibration" of trust is the correspondence between a person's level of trust in the automation and the automation's actual capabilities ([Lee and See, 2004](#)). Better calibration will occur when an operator has an accurate understanding, or mental model, of how an automated system actually works.

"Overtrust" in a system reflects poor calibration in which trust exceeds system capabilities ([Lee and See, 2004](#)), a phenomenon also known as "automation complacency" ([Parasuraman, 2000](#)). "Misuse" of automation refers to the failures that occur when people inadvertently violate critical assumptions and rely on automation inappropriately.

Rapidly developing sensor and tracking technology is being used to design and enable advanced driver assistance systems. Numerous aspects of the driving task have been assisted or automated, e.g., lane keeping, vehicle following (adaptive cruise control), blind spot detection, hazard detection while reversing, wayfinding, and automated braking to name the best known. As an example, one study showed that it may be possible to address some highway design problems with in-vehicle active warning devices. In total, 14 young drivers were monitored on an approach to an intersection near an arch-shaped bridge, where traffic crashes had often occurred due to poor visibility. Image and/or voice warning information was triggered by the presence of a stopped vehicle at the downhill road section of the intersection. Dynamic warning (that there was a vehicle ahead) was more effective than static warning (that there was a traffic signal ahead) in reducing decelerations greater than 0.2 g (Zhang et al., 2009).

High levels of automation have been present in aviation for some time, on occasion exceeding operators' understanding of exactly what the system is doing. The trust that aircraft pilots have in onboard automated systems determines whether they will rely on, or override, a system (Riley, 1989). A pilot's self-confidence, or evaluation of their own capabilities to perform what the automated system can do, also influences their use and trust of automation. If self-confidence is higher than trust, pilots will shift their preference from automatic to manual control, especially in risky situations. As with all transportation modes, designing interfaces and training that effectively provides pilots with accurate information regarding the purpose and performance of automation will enhance the calibration of pilots' trust.

Test Methods: Naturalistic Studies

Naturalistic driving studies represent a new experimental paradigm, which allows a greatly improved understanding of how various driver behaviors contribute to crashes, and how drivers respond to traffic control devices and interact with the roadway as well as how drivers respond to distractions such as cell phones and video advertising signs. Naturalistic studies involve large numbers of drivers having their personal vehicle instrumented with sensors and cameras to record many aspects of their driving behavior in minute detail, including near-crashes and crashes. The 100-car pilot study was the first of these (Klauer et al. 2006). Since then, a much more ambitious collection of over a year's worth of data from 3500 drivers in six states has been completed as part of the Strategic Highway Research Plan 2 administered by the Transportation Research Board (TRB). An example study using these data is one on distraction mentioned earlier (Victor et al. 2015). In addition to the driver data, roadway and roadside characteristics of about 12,000 miles traveled by study participants were collected. A roadway data collection vehicle drove selected roads at posted speeds and recorded roadway geometry (horizontal curvature information, grade, cross slope, lane, and shoulder information), speed limit signs, and intersection locations and characteristics.

Human Factors Guidelines

The US TRB's National Cooperative Highway Research Program (NCHRP) Report 600: Human Factors Guidelines for Road Systems: Second Edition provides data and insights on the extent to which road users' needs, capabilities, and limitations are influenced by the effects of age, visual demands, cognition, and influence of expectancies (Campbell et al., 2012). NCHRP Report 600 provides guidance for roadway location elements and traffic engineering elements. For example, in the section on nonsignalized intersections, considerations underlying required sight distance at right-skewed intersections are discussed, and in the section on signalized intersections, guidelines are given concerning the restriction of right turns on red to address pedestrian safety, and the accommodation of vision-impaired pedestrians at roundabouts.

Distraction-related guidelines also exist. In Canada in 2019, Transport Canada introduced their Guidelines to Limit Distraction from Visual Displays in Vehicles (Transport Canada, 2019). These guidelines followed the introduction in 2013 of the US NHTSA's voluntary Guidelines for Reducing Visual-Manual Driver Distraction during Interactions with Integrated, In-Vehicle, Electronic Devices (National Highway Traffic Safety Administration, 2013).

Legalization of Marijuana

Possession of marijuana is legal in a number of US states and, since October 2018, in Canada. This raises concerns about traffic safety and the need to, as has been done for alcohol, establish a legal limit. The active ingredient in marijuana is THC. A crash responsibility analysis was carried out for a sample of 3005 nonfatally injured motor vehicle drivers in British Columbia, Canada. There was no evidence of increased crash risk in drivers with THC < 5 ng/mL. Although nonsignificant results are not generally highlighted, the researchers report a statistically nonsignificant increased risk of crash responsibility (OR = 1.74) (95% CI = 0.59–6.36; $P = .35$) in drivers with THC $\geq$ 5 ng/mL.

A concern is the lack of correlation between the level of THC in blood, the dose that was ingested (smoking or eating) and performance impairment. Presence of THC in the blood indicates recent use except for chronic users who may show positive levels after several days of not using. There are few studies that test for extended effects of marijuana and so little guidance of how long operators should wait between consumption and return to work. This is particularly challenging in the case of operators using medical marijuana.

Pilots in Canada are restricted from using cannabis before flying. On June 3, 2019, Transport Canada announced a new policy stating that flight crew (pilots and flight engineers) and flight controllers (air traffic controllers) would be prohibited from the use of cannabis for at least 28 days before being on duty. In other transportation modes like rail, where many operating employees are

perpetually on-call, most companies have “zero tolerance” policies in place that require employees to be fit for duty, including not being impaired by THC.

Expert Systems

Recent years have seen the evolution of expert computer-based systems that have potential to improve transportation safety using various approaches, from providing direct feedback to users on their physiological state, to informing shift scheduling and work planning to optimize human performance, to proactively identifying crashes and incidents that could compromise safety and learning from their outcomes before an accident happens. Some of these systems are presented here.

Tools that Provide Feedback to Operators

Fatigue

There are wearable devices available that inform users as to their likely state in terms of sleep-related fatigue. For example, the Readiband is a wrist-worn device that measures sleep using an accelerometer that records wrist movement. Known as actigraphy, this technology estimates when a wearer is asleep *vs.* awake. While the algorithms used by the Readiband and the software that generates and provides feedback to wearers are fairly accurate, it can be challenging to differentiate between being still and being asleep. Regardless, these types of wearable technology show promise in their potential to improve safety.

Driving

Video- and sensor-based driver feedback systems encourage safe driving by providing drivers, often across company fleets but also for specified driver groups such as older or teen drivers, with in-vehicle feedback and video-based coaching. These systems can be used by drivers themselves, parents, or fleet managers to inform safety culture and provide incentives regarding driver safety. Driver rankings, data-driven rewards programs, and training are outcomes that can be used to improve overall safety.

Tools to Inform Planning

Fatigue Scheduling Systems

There are several software decision aides available today that were designed to assess and forecast performance, based on variables such as sleep restriction and time of day, to design work (and sleep) schedules to reduce the risk of fatigue and the resultant performance decrements. Based on biomathematical models developed by the military, the accuracy of the tools in predicting fatigue is significant. For example, the Fatigue Avoidance Scheduling Tool (FAST) was developed by the United States Air Force in 2000–2001 to address the problem of aircrew fatigue in aircrew flight scheduling. FAST software displays work and sleep data entry in graphic, symbolic (grid) and text formats, to shows cognitive performance effectiveness as a function of time. The calculated performance effectiveness represents composite human performance on a number of cognitive tasks, scaled from zero to 100%. The goal of the user/scheduler is to keep performance effectiveness at or above 90% by manipulating the timing and lengths of work and rest periods.

Tools that Inform Safety Countermeasures

Road

Safety Analyst is a set of software tools used by state and local highway agencies for highway safety management. Safety Analyst was developed by FHWA (US Federal Highway Administration) in cooperation with participating state and local agencies and is available through AASHTO (American Association of State Highway and Transportation Officials). Safety Analyst automates procedures to assist highway agencies in implementing the highway safety management process, including: network screening, diagnosis, countermeasure selection, and evaluation. The diagnosis tool guides the user through a series of questions answered by means of office and field investigations concerning how the driver is likely to interact with the traffic control devices and highway design, the potential for driver error and appropriate countermeasures.

Railway Level Crossing Safety

Federally regulated railway companies and road authorities in Canada are jointly responsible for the maintenance and safety of level crossings. Transport Canada’s Grade Crossing Inventory uses an internal web-based analysis tool to compare crossings against each other and identify those that are most in need of safety improvement. The tool assesses the following risk factors:

- TSB data on rail occurrences;
- the volume of road and railway traffic;
- maximum train and vehicle speeds;
- number of tracks and lanes;
- urban or rural environment; and
- warning systems in place at the crossing (i.e., gates, bells, lights).

Aviation

The US Aviation Safety Reporting System captures confidential reports, analyzes the resulting aviation safety data, and disseminates vital information to the aviation community. It brings together government, industry, and individuals in the aviation community to maintain and improve aviation safety by collecting voluntarily submitted aviation safety incident/situation reports from pilots, air traffic controllers, and others. The system acts on the information in reports by identifying system deficiencies and issuing alerting messages to people who are in a position to correct them, and by educating more generally through a regular newsletter, a scientific journal, and through its research studies.

In-Depth Traffic Accident Investigation

In-depth traffic accident investigations are done in the airline, railroad, and shipping industry, as well as for select roadway crashes. This article focuses on roadway crashes only. An in-depth traffic accident investigation is a multi-interdisciplinary work, in which a large number of accident-related variables are collected from each level of road traffic system (Fig. 1). In-depth traffic accident data contribute to improving the road design, vehicle safety, medical services, traffic management, etc.

Governmental agencies as well as nonprofit and industry-lead investigations are done. To help find the causes of auto accidents and fatalities, Volvo established the industry's first in-depth auto accident investigation team in 1970. The Volvo safety teams annually investigate 100 accidents at the scene, immediately after they occur and another 2500 accidents are analyzed statistically each year. Already by the year 2000, Volvo's safety division has accumulated data on 28,000 crashes involving Volvo cars carrying more than 40,000 occupants. In Finland, all fatal road traffic accidents are investigated at the site by multidisciplinary Accident Investigation Teams (based on the Act on the Investigation of Road and Cross-Country Traffic Accidents from 2001). The Finnish Motor Insurers' Centre maintains the investigations. The purpose is to find out what happened in the accident, uncover risk factors, and give safety recommendations. Moreover, various in-depth traffic accident investigation projects also have been established in other countries, such as the German In-Depth Accident Study (GIDAS) project, China In-Depth Accident Study (CIDAS) project, and Crash Injury Research and Engineering Network (CIREN) project.

Haddon Matrix Model, a "three factors and three phases" theory, is often used to analyze the accident causations and corresponding prevention countermeasures (Haddon, 1968). Based on the analysis model, in in-depth traffic accident investigation, a whole traffic accident process is divided into three phases: precrash, crash, and postcrash. Precrash stage is divided into two intervals: (1) the interval between normal driving and danger detection, mainly includes participants' driving states (e.g., emotion, drinking, and visual obstacle); and (2) the interval between danger detection and crash occurrence, mainly includes participants' judgments (e.g., estimating the behaviors of other traffic participants) and participants' decisions (e.g., braking and steering). Crash stage refers to the interval between crash occurrence and eventual stopping, mainly includes initial impact parameters (e.g., impact speed and contact positions between participants), participants' decisions (e.g., braking and steering), and participants' impact responses (e.g., pedestrians' motions during a collision). Postcrash stage refers to the afterward disposal of a traffic accident, mainly includes the accident consequences (e.g., final positions of participants, vehicle damage information, and human injury information).

With the development of vehicle automation and electrification, precrash parameters, especially the driving psychology and driving behaviors, have attracted increasing attention. A series of analysis methods were proposed to further understand the driving psychology. Especially, the human failure model (HFF), allowing the classification of the driving functional failures (e.g., human errors and capacity exceeding) and of the factors of these failures, distinguishes five major functional categories within which can be identified the incapacity of a function (perceptive, diagnostic, prognostic, decision-making, and action-taking) to overcome a difficulty encountered by the traffic participant (Van Elslande and Fournier, 2017).

Accident video is an effective tool to accurately acquire precrash driving behaviors. In the view of requirement of the automobile industry, some neonatal in-depth traffic accident investigation projects are initialed, such as the Traffic Accident Investigation and Research in China (TAIRC) project—it focuses on these accidents captured on video or involving electric/autonomous vehicles. However, vehicle-mounted video cameras are often present in commercial vehicles such as buses and limousines but typically not in private vehicles in most countries. Also, video recordings of intersections are fairly common, but few segments between intersections have recordings of what actually happened in a crash. We do, therefore, have a long way to go to achieve this goal around the world.

Accident Epidemiology Analysis

Accident epidemiology analysis mainly includes: (1) the analysis of the development tendency and distribution regularities of traffic accident in a specific region. With the development of high-precision maps, the analyzable specific regions are becoming smaller and smaller, and the analyzable influencing factors are getting larger and larger; (2) the exploration of effects of various driver,

Figure 1 Road traffic system.

pedestrian, and neighborhood factors (e.g., gender, age, economy, etc.) on accident severity, in which the classification of influencing factors is the research emphasis.

Statistical analysis, based on in-depth accident data, is the most fundamental means of investigating the crash characteristics and mechanisms. Epidemiology is a subject of investigating the distribution and determinants of health-related conditions and events in a specific population, and the strategies and measures of preventing disease and improving health. This research can be divided into two categories: descriptive and analytic epidemiology. A reasonable accident epidemiology analysis can be achieved with the different types of accident data categorized based on accident type (e.g., vehicle-vehicle and vehicle-pedestrian accidents), accident region (e.g., urban and rural), road section (e.g., straight road, curve, and junction), etc. Descriptive accident epidemiology focuses on basic characteristics of any particular type of crash-related events, such as what, who, when, and where, which reflects the central tendency and discrete degree of each parameter. Analytic accident epidemiology attempts to excavate the contributing factors of any particular type of crash-related events, such as which and how, which reveals the effect of each parameter on crash severity.

Over the decades, lots of research has been conducted to analyze crash severities. In these crash-severity models, the causal factors are defined from the perspective of driver, vehicle, roadway, and environment, such as driver behaviors, vehicle performance, traffic control elements, visibility conditions, and so on. The dependent variables are either a binary outcome (e.g., fatal and nonfatal) or a multiple outcome (e.g., fatal, seriously injured, slightly injured, and noninjured). And the dependent variables with multiple outcomes can also be differentiated as ordinal outcomes (considering the order of injury-severity levels) and nominal outcomes (e.g., unordered). The appropriate statistical methodology is selected based on data characteristics: (1) underreporting of crashes, (2) ordinal nature of crash severities, (3) fixed parameters, (4) omitted variable bias, (5) small sample size, (6) endogeneity, (7) within-crash correlation, and (8) spatial and temporal correlations. The existing crash injury-severity analysis models are broadly divided into three categories: binary outcome model, ordered discrete outcome model, and unordered multinomial discrete outcome model. Lots of variations of primitive models have been conducted to achieve concrete analysis targets (Savolainen et al., 2011).

Based on simple binary outcome models, the Bayesian hierarchical binary logit model and simultaneous binary logit model are proposed to obtain more accurate parameter estimations by considering injury correlations when investigating the injury-severity levels of multiple individuals involved in same crashes. The bivariate and multivariate binary probit models are developed to deal with these cases in which explanatory variables could be endogenous in regard to injury severity, such as drivers' decisions to a vehicle with airbags or antilock brakes may be related to crash possibility and injury severity, because the endogenous variables directly as explanatory predictors will cause biased parameter estimations. Traditional ordered discrete outcome models have two obvious drawbacks: (1) they are particularly vulnerable to underreporting of crashes; and (2) they place on the way variables influence outcome probabilities. On the basis of traditional ordered probability models, a copula-based multivariate approach is applied to analyzing the injury-severity levels of multiple individuals involved in same crashes. Bivariate ordered probit model, which essentially is a layered architecture of two equations that reflect a simultaneous relationship, is used to address these issues of endogeneity. One assumption of ordered outcome models is that the error variances are homoscedastic. Heterogeneous choice model is established to solve the possibility that error terms may be heteroskedastic with respect to injury severity. Another assumption of ordered outcome models is that the parameter estimations are constant across injury-severity levels. Generalized ordered logit model is built as an alternative when the assumption is violated. Unordered multinomial discrete outcome models, which do not consider the ordinal nature of injury-severity outcomes, have attracted increasing attention, because they are not affected by these restrictions existing in traditional ordered logit and probit models. Multinomial logit models, which include three or more outcomes and do not consider the ordering of injury-severity levels, are the most basic unordered discrete outcome models. However, the models are particularly vulnerable to correlation of unobserved effects from one injury-severity level to another. The correlation results in a violation of the model's independence of irrelevant alternatives (IIA) property. Sequential logit and probit models, which essentially are generalized standard ordered logit and probit models, allow the treatment of the severity thresholds across the ordered response levels by separate parameter coefficients for explanatory variables and heterogeneity in the effects of injury-severity determinants. Nested logit models, in which the injury-severity levels are partitioned into nests that consist of injury-severity outcomes that share some unobserved elements specific to only those outcomes, overcome the IIA limitation of multinomial logit models and improve the sequential logit model by allowing for correlations among error terms across different injury-severity levels. Except these common methods, various novel methods have been used to analyze the injury-severity levels, such as artificial neural networks and classification and regression tree approach.

Accident epidemiology analysis technology is becoming more systematic, refined, and hierarchical. Establishing a decision support system by integrating traffic accident data and other multisource big data is the future development trend, which can be used to analyze the contributing factors related to traffic accidents and predict the traffic security situation in a specific region.

Traffic Accident Reconstruction

Traffic accident reconstruction, based on in-depth accident data, is an important approach of understanding the accident mechanisms and impact responses of participants. It is easy to build targeted prevention countermeasures that comparatively analyzing the differences between different types of traffic participants (e.g., pedestrian, bicyclist, and motorcyclist) in impact responses by traffic accident reconstruction (Peng et al., 2012). It can be classified into inverse accident reconstruction (calculating inputs according to known outputs) and forward accident reconstruction (calculating outputs according to tentative inputs). Inverse accident reconstruction, which is essentially theoretic calculations by mathematical equations, was originally used for accident identification. Based on accident scene information (e.g., braking distance and pedestrian throw distance), vehicle damage information (e.g., the deflection of windshield plate), and human injury information (e.g., pedestrian head injury severity), some impact parameters (e.g., vehicle crash speed) can be obtained through inverse accident reconstruction using the kinetic energy conservation law, the momentum conservation law, etc. However, there often are larger computational errors since the mechanical models used in this method are too simplistic. And the integrity of this method is poor—only obtain a certain parameter value at some point. With the development of computer technology, numerical simulation is applied to traffic accident reconstruction. Based on corresponding environment, vehicle, and human models established in numerical simulation platform, forward accident reconstruction can restore a whole accident process by tentatively entering appropriate impact parameters. Forward accident reconstruction is more reliable and integrated compared with inverse accident reconstruction. However, the reliability of results generated by this method is often detracted since some impact parameters (e.g., the position of impact point) are hard to accurately confirmed and measured at accident scene.

Traffic accident reconstruction can be broadly divided into three phases: information collection, information extraction, and accident reconstruction. To improve its reliability, lots of researches have been conducted from the earlier three aspects. For example, the Unmanned Aerial Vehicle (UAV) and Event Data Recorder (EDR) have been applied to accident investigation to collect more detailed and accurate accident information. The video parameter extraction method has been continually improved to obtain more reliable accident data. For accident reconstruction, the total uncertainty of reconstruction results has three origins: (1) the uncertainty in measurements—lots of typical measurements taken by investigators on the place of collision follow normal distribution; (2) the uncertainty in calculation refers to the scatter of the values of some parameters (e.g., the driver's response time and friction coefficient) that are not measured directly but taken from tables; and (3) the uncertainty of modeling occurs when two or more mathematical models give different analysis results with respect to same physical problem (Wach and Unarski, 2007). Especially, to understand the effects of random variable uncertainty on unknown variable uncertainty, various uncertainty analysis methods have been applied to quantify the sources of uncertainty and propagate the uncertainty from random variables to unknown variables through mathematical models of physical problems. These methods can be classified into two categories: (1) deterministic methods, such as Total Differential Method (TDM), Upper and Lower bound Method (ULM), Finite Difference Method (FDM), and Response Surface Method (RSM), by which the ranges of reconstruction results under a certain confidence level can be obtained; and (2) probabilistic methods, such as Gauss Method, Methods with the Use of Stochastic Processes, Probabilistic Perturbation Method, and Monte Carlo Method (MCM), by which the probability distributions of reconstruction results can be acquired (Cai et al., 2014).

Forward accident reconstruction is essentially a highly user-interactive and time-consuming tentative solving process, in which investigators need to constantly adjust the crash parameters to make the collision results (e.g., the contact position between participants and the final position of each participant) coincide well with the actual. Furthermore, whether the reconstruction results are acceptable is subjectively determined by investigators, which reduces the persuasion of reconstruction results largely in accident responsibility cognizance. To improve the efficiency of accident reconstruction and the reliability of reconstruction results, a viable solution is the optimization technique (Untaroiu et al., 2009). Especially, a collision optimizer has been integrated into PC-Crash—a widely used traffic accident reconstruction software (Moser et al., 2003).

The automatic driving simulation test, namely establishing a mathematical model containing static actual environment and dynamic traffic scene and then testing an automatic driving algorithm in the virtual traffic environment, is an important tool of examining the safety of autonomous vehicles. It can be easily obtained from traffic accident reconstruction that the kinematics parameters of each participant before a collision, which contributes to constructing accurate precrash accident scene. Integrating traffic accident reconstruction and automatic driving simulation may be a future development trend.

Injury Biomechanics Investigation Methods

Biomechanics is a multi-interdisciplinary subject in which the mechanics connects engineering with medicine. These methods exploring the injury biomechanics of traffic participants mainly include animal experiment, cadaver experiment, mechanical model experiment (dummy and subsystem impactor experiments), and computer numerical simulation.

Injury researches using anesthetized animals instead of human can obtain important injury data of some special parts (e.g., brain and spine). However, investigators have to consider lots of effect factors when extrapolate human injury data from animal

experiment data, since there are significant differences between human and animals in size, constitution, etc. To weaken the restriction, most animal experiments were conducted using primates most similar to human (e.g., monkey and chimpanzee). For instance, some researchers stunned 45 monkeys by accelerating their heads along the oblique, sagittal, lateral direction and found it was consistent that the symptoms between human and monkeys in coma and axonal injuries (Gennarelli et al., 1982).

Human cadaver experiment, also known as past mortal human subject test, is an important approach for investigating human injury biomechanics and verifying the validity of mechanical test model and mathematical simulation model. Compared with animal experiment, the material of a human cadaver is anthropologically identical to that of a living person. However, the death time and cadaver preparation technique have an impact on the experiment results. Additionally, the physiological response and muscle strength of a cadaver cannot be determined, and the characteristics of human tissue vary as people age. Even so, this method is still widely used to evaluate the validity of various mechanical and mathematical models. For instance, some researchers impacted head-on the frontal part of a human cadaver without preservative treatment with a rigid cylinder and comparatively analyzed the relationships between intracranial pressure and striking speed and energy under different impact conditions (Nahum et al., 1977). These experimental data have widely used to access the reliability of various head finite element (FE) models.

Compared with human cadaver experiments, mechanical model experiments have advantages of high repeatability and test convenience. At present, automobile safety evaluations around the world mainly rely on subsystem impactor experiment aiming at pedestrian safety and dummy experiment with respect to occupant safety, since these devices and dummies are similar to human in size, structure, mass distribution, dynamic characteristic, and impact kinematics, and the impact responses of some key parts have a certain degree of biomechanical fidelity. The subsystem impactor experiment was proposed by the European Enhanced Vehicle Safety Committee Working Group WG10 and WG17 to evaluate the protection performance of the vehicle's front structure for pedestrian. A legform impactor is used to investigate the impact between lower limb and bumper, which can measure the tibia acceleration, shearing displacement, and knee-bending angle. An upper legform impactor is used to investigate the impact between pelvis and bonnet's leading edge, which can measure the contact force and bending moment. And the adult (4.8 kg) and child (2.5 kg) head-form impactors are used to investigate the impact between head and bonnet, which can measure the head acceleration at the head gravity. Based on the EEVC's proposal, the International Standards Organization (ISO) also proposed a pedestrian subsystem impactor experiment, in which the adult and child head-form impactors were adjusted to 4.5 kg and 3.5 kg, respectively. To improve pedestrian safety from the government and consumer perspectives, the subsystem impactor experiment has been accepted as a regulation and new car assessment program (NCAP).

With the development of computer technology, numerical simulation has been widely applied to crash injury investigation. Currently, the commonest numerical models include: multi-body system (MBS) model, in which the segments are modeled as a rigid body and connected with several joints, and FE model, in which the human body is modeled based on the constitutive properties of human tissues. The advantages of the MBS model are low calculating cost and appropriate for accident reconstruction. For instance, the TNO models have been widely used in real-world pedestrian accident reconstruction. The disadvantages are: (1) each body part in the MBS model is represent by an approximate ellipsoid, which reduces the accuracy of impact responses; and (2) the MBS model can only be used to investigate the injury mechanisms from the perspective of kinematics, such as velocity, acceleration, and impact force, but cannot be applied to evaluating the injury severities from the level of tissues. The FE model can describe irregular human body geometry, complex anatomic structure, nonuniform nonlinear material property, variable boundary and loading conditions, and so on, which contribute to obtaining more accurate impact responses and intensive injury mechanisms. At present, the human FE model becomes increasingly subtle and anthropomorphic with the help of CT scanning and human slice techniques. And the neuromuscular responses in different crash scenarios are also considered. As the most advanced full-scaled model in the world nowadays, the THUMS Version 6 has not only detailed viscera models, but also muscle models that can simulate various strength levels when a driver is in different emotional states (e.g., tense and relaxed). The model can adapt the variety of occupant sitting posture with the popularity of autonomous vehicle, then achieves more accurate analysis.

Injury Mechanisms and Criterion

The head, chest, and lower extremities are the most frequently body parts injured in traffic accidents. To meet the need of engineering designs to reduce and even avoid accidental injuries, the injury mechanisms and corresponding tolerance levels of various body parts have been comprehensively investigated from a biomechanics point of view.

The common head injury patterns are skull fractures and brain injuries. Skull fractures include basilar and vault fractures, which are caused by the contact force. Brain injuries can be classified into two categories: diffuse and focal injuries. Diffuse injuries consist of concussion and diffuse axonal injury (DAI). Concussion is the most common injury stemming from a sharp shock or pressure. DAI refers to the disruption to the axons in the cerebral hemispheres and the subcortical white matter. Focal injuries consist of hematomas and contusions, which refer to localized damage to blood vessels and/or neurological tissue. Hematomas can be epidural, subdural, or intracerebral, while contusions can be coup or contrecoup. The noncontact rotation or translation motion of the head, which leads to a relative movement between skull and brain, often causes brain injuries. The head injury categories and corresponding mechanisms are summarized in Table 1 (Yang, 2005).

For skull fracture, the contact force has been widely adopted as a predictive indicator with different tolerance limits for different impact locations, such as 3.6–9.0 kN for frontal, 5.0–12.5 kN for temporoparietal, 6.4 kN for occipital, etc. Recently, some

Table 1 Typical head injuries and corresponding injury mechanisms

<i>Injury categories</i>	<i>Injury mechanisms</i>
Skull fracture	Contact force
<i>Brain neurological injuries due to tearing of neuronal axons in the brain tissues</i>	
Concussion	Rotational motion and relative motion between skull and brain
Diffuse axonal injury	Rotational motion
<i>Intracranial vascular injuries due to ruptured arteries and/or bridging veins</i>	
Coup contusion	Contact force
Contrecoup contusion	Pressure wave
Epidural hematoma	Contact force
Subdural hematoma	Translational and rotational acceleration

researchers found the skull internal energy was an excellent candidate to predict skull fracture. The 50% risk of skull fracture for different locations: 481 mJ for frontal, 456 mJ for temporoparietal, and 457 mJ for occipital, respectively (Sahoo et al., 2016b). For brain injuries, the predictive indicators related to brain tissue strain perform better compared with that related to translation or rotation of head. This brain injury criterion mainly contain Von Mises stress, first principal stress, Von Mises equivalent strain, first principal strain, and cumulative strain damage measure (CSDM) at three different strain levels, such as CSDM (0.10), CSDM (0.15) and CSDM (0.25), maximum axonal strain rate, and maximum axonal strain (Sahoo et al., 2016a). Thoracic injuries can be divided into three categories: ribcage fractures, lung injuries (pneumothorax or hemothorax), and injuries of the other thoracic organs. The thorax injuries are mainly from two mechanisms, namely the compression of the thorax and the viscous loading within the thorax cavity. The compressive force to the thorax can cause the rib fracture, sternum fracture, a hemothorax, and pneumothorax. The viscous and inertial loading can cause lung contusion and vessel disruption. Thorax injuries in crashes often occur in combination with combined mechanisms. The thoracic trauma index (TTI) and viscous criterion (VC) were introduced to access the thoracic injuries. A TTI value of 85 g has been proposed as the maximum exposure for adults and 60 g for children, while a VC_{max} value of 1 m/s is the recommended maximum exposure for adults.

Pelvis injuries often derive from a lateral impact with stiff bonnet edge or bonnet top. The lateral loading from the car front structure is applied to the great trochanter of the femur, resulting in compressive injuries. The injuries to the pelvis involve one or more of the bone structures, namely pubic rami, pubic symphysis, acetabulum (hip socket), femoral head, and proximal femur. An average lateral impact force caused skeletal injuries: 4 kN for 5th percentile females and 10 kN for 50th percentile males.

Typical lower limb injuries include fractures of the long bones (femur, tibia, and fibula), injuries of the knee joint (ligaments avulsion and condyle fractures), and ankle dislocation and foot bone fracture. The long bone fractures are mainly caused by lateral shearing and bending.

Knee joint injuries mainly contain femoral/tibia condyle fractures, patella fractures, and ligament tears and ruptures. These injuries are mainly caused by the force transferred through the knee joint as a result of shear loading and/or bending loadings, or a combination of both. When the knee joint is exposed to a bend loading, the medial collateral ligament (MCL) is first stretched; if the bending moment goes beyond the tolerance, the MCL could be partly or totally ruptured. Then other ligaments (anterior cruciate ligaments, posterior cruciate ligament, lateral collateral ligament) may be fractured.

Safety plays a key role in aviation operations. From the safety point of view, an airplane can be a significant source of danger for passengers on board of the airplane, and people on the ground. During a normal flight, an airplane may be affected by numerous factors that may cause an incident and potentially lead to a catastrophe. In aviation, the safety of a flight is determined by the level of threat to human life, estimated by a probabilistic approach. The effect of each destabilizing factor is assessed as a risk of harm to the human body and is also compared with a certain level of acceptable risk for the safety of air transport. The most significant aviation event is a catastrophe, defined as an event that has led to the death of a person or their disappearance. Aviation events without human casualties but resulting in a significant damage or destruction of airplane structure, or serious to a person, are defined as an accident. An incident is an event that does not result in a catastrophe, accident, or serious incident, which took place during the airplane operation, resulting in a deviation from the normal operation of the airplane, crew, or Air Traffic Management services, and was under the influence of certain factors. Serious incidents include events that require a crew to take complicated or emergency actions that usually would not be taken during a normal flight.

The results of the analysis of aviation events indicate that, in the most cases, incidents appear due to the effect of factors that consistently degrade the flight state. The major number of incidents and catastrophes is the result of a combination of contributing factors associated with airplane performance, crew activities, and environmental conditions (Lee and Kim, 2015; Yu and Wang, 2019).

In the general case, the detection of near incidents is based on the detailed analysis of physical values that determine the airplane state (Fig. 1). Numerous sensors measure physical values that are presented in the digital form at the time of discretization. As sensor measurements contain errors, which are usually normally distributed, it is necessary to perform errors filtering in order to reduce the noise impact of further computations. During filtration, different stages can be used including data fusion algorithms, detection of outliers, statistical data processing, and methods for reduction of measurements errors. Results of filtration are used for calculation of the airplane parameters that describe its state.

The values of parameters are compared with the boundaries of a certain safety category, which serve as an indicator of near-miss detection of degrading changes in a state. During near-miss detection, simple algorithms for comparing values with permissible confidence band and complex algorithms, such as probabilistic one, grounded on risks estimation of dangerous situations, can be applied. A risk is the probability of a dangerous state, which has a threat to human life.

In probabilistic methods of risk analysis, a Bayes formula is usually used to estimate the risk of danger taking into account prior information obtained on the basis of previous experience of system operation (Ostroumov and Kuzmenko, 2018a). Detection of near-miss conditions is performed due to a simple comparison of the estimated risk with the value of acceptable risk, defined by regulative documents in aviation, or the results of statistical research, or expert assessments. Also, probabilistic methods are usually based on the maximum posteriori estimation, which provides near-miss detection with the highest probability of deviation from an acceptable level. Results of the near-miss analysis are displayed to the pilot through the Electronic Flight Instruments System (EFIS) on the scales of a parameter in the form of acceptable areas, which are highlighted with a color in accordance with the level of danger.

An oral and visual warning of an unsafe state for a pilot allows preventing further degradation of flight safety and requires a pilot to take a series of actions aimed to return the parameters to the acceptable limits. As an aircraft is a complex dynamic system, which is characterized by multiple numbers of different parameters, they are controlled automatically by built-in control systems to reduce the pilot workload.

Different systems of incident detection and avoidance are used for recognition and alarming of potential hazards in civil aviation.

An airplane engine is a complex system with a high danger of fire and explosion, which requires continuous control of numerous engine parameters. In particular, the Full Authority Digital Engine Control System (FADEC) controls gas pressure and temperature in different zones, estimates the thrust using measurements of different velocities, measures vibration parameters, and controls temperature and pressure of oil and fuel in different engine zones. Going out of the operation boundaries, deviation of parameters involves the automatic control algorithms that adjust parameters in order to reduce the risk of developing a

Figure 1 Near-miss detection and management.

hazardous state and minimizing degradation of engine performance. A pilot controls only the engine thrust and does not need to spend the time to monitor other engine parameters. FADEC provides measurement, near-miss analysis, and integrated control of airplane engine operation.

Fire in the engine compartment is one of the severe hazardous states, which can occur due to engine elements overheating, faults, the presence of external physical objects inside the engine, and other causes. The simple presence of a small amount of fuel or oil on a heated engine surface can lead to an instantaneous fire and engine failure. An onboard fire detection system is used for fire detection at the engine bay and adjacent compartments in order to prevent the spread of the fire to other parts of an airplane and to the fuel tanks. Numerous sensors of temperature measurements and open flame detectors are used at different engine zones in the fire protection system. The sectoral structure of the engine and sensor locations allows the system to precisely identify a zone within which the combustion is detected. In case of fire detection, a fire protection system alarms the pilot about the danger in the form of audiovisual warnings with a subsequent engine stop and interruption of fuel supply with the purpose of fire localization and prevention of fire rapidly spreading to other parts of the airplane. Depending on the fire location, a pilot initializes a fire extinguishing system that involves mixing chemical substances in containers and forms a foaming substance with its subsequent spraying in the engine burning zone.

The fuel system is another important source of the airplane safety threat. Fuel by its technical characteristics is a combustible substance, which is an additional explosive threat onboard of the airplane. Engine operation needs a large amount of fuel supply. The fuel consumption creates empty spaces in the fuel tanks, which can lead to conditions for the accumulation of hazardous gases that, at certain concentrations, may constitute a threat of explosion. Prevention of explosion is grounded on control of the pressure inside of fuel tanks and oxygen percentage to the total amount of dangerous gases with the purpose of avoiding the explosive concentration. Air separation modules or pumped inert gas can be used for reduction of explosive gas concentration.

In addition to potential explosions, fuel consumption is a threat of airplane balancing and stabilizing, which is associated with a nonuniform distribution of fuel mass in different parts of the airplane. To overcome this threat, fuel division to multiple small tanks is used. Thus, modern aircraft may include more than 20 fuel tanks distributed in a balanced way along with the airplane structure. Fuel usage in one place requires the initiation of fuel pumping in all other tanks for a uniform allocation of a fuel mass, which remains in the fuel system in order to balance the aircraft state.

Another danger for passengers is high-altitude flying in the conditions, such as rarefied air, low pressure, and low temperatures. Therefore, a passenger cabin must be completely isolated from the environment and several systems, such as air conditioning and pressurization should create the comfortable conditions for people present onboard of airplane to support a predefined temperature, air structure, humidity level, and air pressure. Cockpit and cabin design has to follow specific requirements for mechanical elements of structure and sealing of seams regarding a significant pressure difference inside and outside the airplane. A small crack or hole in the cabin body may cause a sudden airflow, which rapidly increases the load on the edge of the crack and leads to rapid destruction of the airplane. Decompression of the passenger cabin at high altitude leads to air loss and creates a serious threat to passengers and crew (Brot, 2018). Lack of sufficient oxygen supply for breath leads to the state of hypoxia that can result in fatal processes in the human body and brain. Emergency oxygen system supplies sufficient oxygen level for human surviving in case of decompression, supplying a certain mixture of oxygen through the emergency respiratory masks. The emergency oxygen system is initiated automatically after detection of a sharp reduction of pressure in the cabin. Cockpit decompression is a serious threat for pilots because the inability to wear an oxygen mask or fault of emergency oxygen system can lead to a loss of pilot's consciousness, which can be resulted in hypoxia and a loss of the ability of airplane control.

Airplane icing is another serious factor that significantly reduces the aerodynamic performance of an airplane and can cause loss of control and leads to catastrophe. An ice formation on the aerodynamic surfaces is a result of the effect of precipitation on the ground or getting chilled drops of moisture during the airplane passing through the cloud layer and the action of low temperatures. The anti-icing system contains numerous ice sensors on the main aerodynamic surfaces and the engine. In the case of ice detection, the system initiates the appropriate warning in the cockpit according to the rate of ice accumulation. Anti-ice system may utilize different approaches for reducing the ice accumulation rate, such as hot airflow through structural elements, electric heating, or

spraying liquids through certain holes on the airplane surface, which reduce the freezing point. Heating of structural elements or vibration of a certain flexible surface can be used in order to reduce the amount of already accumulated ice.

Flight Management System

Several incidents detection algorithms are included in the flight management system (FMS). FMS is an onboard computer system of airplane navigation and flight control. An internal memory of FMS contains various air-navigation databases, including navigational aids, runways, airport data, standard instrument departures, standard terminal arrivals, approaches, and routes. Each FMS has a three-dimensional trajectory of airplane motion that is continuously compared to the airplane location during the flight and is displayed to the pilot at the navigation display of EFIS. Unplanned airplane deviations from the predefined flight plan are immediately detected and displayed to the pilot with automatic calculation of parameters that are necessary to use for airplane return to a planned flight trajectory. FMS checks all of the pilot's actions of airplane navigation and guidance for possible incidents and prohibits pilots to use "wrong" commands. In addition, FMS includes an airplane mathematical model, which is used to estimate the permissible limits of a large number of flight parameters. Thus, after entering the number of passengers and weight of cargo, FMS estimates the most optimal flight level in terms of economy, evaluates the limits for airspeed, and other aircraft parameters, which prevent dangerous states of a flight. The results of FMS operation are shown on the flight and navigation displays on the corresponding scales, limiting the pilot's actions and preventing an incident appearance. Also, data processing of airplane locations measured by different sensors is another important FMS function, because the accuracy of airplane positioning is directly connected with air traffic safety. In case of Global Navigation Satellite System (GNSS) lock, FMS initiates one of the other available standby positioning systems with the criterion of maximum accuracy. For example, the Inertial Reference System or positioning by pairs of navigational aids can be used as a standby system (Kuzmenko et al., 2018; Ostroumov and Kuzmenko, 2018b).

Detection of Incidents Related to the Atmosphere

Environmental conditions also may affect the safety of airplane flight and can cause a catastrophe. Thus, bad meteorological conditions, such as wind shear, humidity, rain, or lightning, reduce the aerodynamic performance of an airplane that can lead to loss of control. Onboard weather radar and meteorological digital data from the ground are used for early identification of dangerous meteorological phenomena and informing the pilots. Aviation meteorological service supports pilots with a troposphere phenomena data, observed by ground meteorological radar, meteorological maps, a map of winds, images of the troposphere in the infrared spectrum, maps of possible icing, and turbulence areas.

Turbulence and wind shear are sources of danger associated with the factors of the troposphere state. A low-level wind shear alert system (LLWSAS) is a ground-based system used to detect wind shear and associated weather phenomena, such as microbursts, close to an airport, especially along the runway corridors. Common LLWSAS is grounded on atmosphere sensing by laser equipment (Hon and Chan, 2014). Detected dangerous areas are warned to pilots and other aerodrome services to avoid entering. Low-level wind shear is a sudden change of wind direction and velocity in different planes. The appearance of wind shear at low altitude may result in sudden airplane altitude drop. Therefore, the warning of LLWSAS helps pilots to respond appropriately. Some airplanes are equipped with a similar onboard wind shear alert systems (WSAS) that provide warnings related to the dangerous wind conditions ahead of the airplane.

Decrease in the maximum visibility range is another important factor that affects aviation safety. In particular, fog is a typical problem of airplane taxing and runway operations. Instrument landing system (ILS) supports airplane landing in case of significant visibility reduction. At the landing phase of a flight, an aircraft has to follow a glide-slope trajectory up to the touchdown point. ILS measures the deviation from the glideslope trajectory and warns pilots about the deviation side and its value. During the whole landing phase, pilots control the deviation from the glide slope to ensure a safe landing. ILS consists of ground-based radio beacons that transmit electromagnetic signals, which define glide-slope trajectory and onboard receivers of these signals for deviation measurements and indication.

An enhanced vision system (EVS) can be used in case of low visibility during airplane taxing. EVS uses infrared or night-vision sensors for visual recognition of taxiways centerlines and boundaries. Airplane location and detected data are used in EVS for warning generation related to deviations from the centerline. In addition, EVS may warn about risky maneuvers and taxi off the pavement to prevent running into obstruction side.

Runway Incursion Avoidance

Airplane runway operation and taxing are associated with the danger of a collision with other aircraft, vehicles on the ground, infrastructure elements, or simple taxi off the pavement. According to the International Civil Aviation Organization (ICAO), a runway incursion is defined as any occurrence at an aerodrome involving the incorrect presence of an aircraft, vehicle, or a person on the protected area of a surface designated for the landing and takeoff of an airplane. Incorrect airplane location can be a result of pilot or vehicle driver mistake to comply with a valid air traffic controller (ATC) clearance or their compliance with an

inappropriate ATC clearance. A system of monitoring and visualization of airplanes and vehicles onto the airport territory supports ATC service. Airplanes and vehicles are equipped with a certain type of transponder to interact with the ground multilateration system to identify localization in the airport area. Automatic Dependent Surveillance-Broadcast (ADS-B) transponders that automatically report vehicle location measured by GNSS are widely used. Vehicle location is processed and displayed on the scheme of the taxiways to support situational awareness of the ATC (Jones et al., 2009, 2010). Hazardous event identification on the ground is based on wide usage of airplane and vehicle path prediction by Kalman filter or simple sequential operations and comparing distances between objects in the closest point of approach with separation minimum taking into account type, size, and speed of moving objects. Predicted deviation out of the taxiway/runway and collisions are immediately warned to the ATC. Ground traffic data are also available to pilots in EFIS and display of vehicle drivers to increase situational awareness and to prevent hazardous operations.

Traffic Alert and Collision Avoidance System

A rapid air transport growth trend has and will continue to increase the number of operated airplanes. This leads to a constant increase in airspace and ground infrastructure load. An airplane operation within the congested airspace is connected with a severe risk of a mid-air collision. Traffic alert and collision avoidance system (TCAS) is an autonomous onboard system of mid-air collision detection and avoidance that improves flight safety (Fig. 2).

TCAS has been proposed by ICAO to be installed on board of airplane since 2000. An air traffic surveillance function of TCAS is based on the principle of secondary surveillance radar (SSR) to measure a relative location of each airspace user. TCAS antenna system transmits interrogation radio signals for an aircraft "mode S" transponder. Each of the aircraft transponders, within the TCAS service volume, generates a response signal at a certain frequency after minor delay. The response signal from airplane transponder contains a digital message that includes information about an airplane identification number and a barometric height (mean sea level). TCAS direction finder equipment measures bearing angles between an airplane centerline and each airspace user. Distances to the airspace users are measured by time of arrival method. Bearing and distance in TCAS, together with a barometric height, decoded from a digital message, allow to precisely localizing air traffic at the polar coordinate system of TCAS. There are two basic types of TCAS.

TCAS I is mandatory for installation on board of general aviation aircraft. TCAS I indicates an air space users' location on traffic display indicator (TDI) in the cockpit to increase pilots' situational awareness. Traffic Advisory on TDI includes airplane markups with a relative barometric height between the airplanes. Also, air traffic data may be visualized on the EFIS or Integrated Navigation System, depending on the equipment list of an airplane. In case of dangerous traffic, pilots cannot use TCAS surveillance data for maneuver planning, because maneuver of collision avoidance can be supported by Visual Flight Rules only in visual contact with the conflicting airplane.

According to international regulations, TCAS II has to be used on board of a large airplane. An air traffic surveillance of TCAS II is identical to TCAS I. However, TCAS II analyzes air traffic for early detection of a possible mid-air collision and automatically generates warnings to the pilots for conflict resolution. TCAS II algorithm analyses airplanes relative motion and, depending on the time of flight to the closest point of approach, generates recommendations for pilots of airplanes involved in a conflict. Conflict resolution between airplanes in TCAS II is performed by coordinated maneuver in a vertical plane. Resolution Advisory (RA) includes audio warnings associated with allowed vertical velocities range. RA increases the time of the pilot's reaction and is obligatory to follow. TCAS II complies with international initiatives of airplane separation minimum supporting in vertical, lateral, and longitudinal directions within a defined airspace structure during conflict resolution. Conflict avoidance is supported

Figure 2 TCAS data on navigation display of B737.

by coordinated data processing between both airplanes with the help of digital data link communication, based on “mode S” technology.

Since 2016, each airspace user has to be equipped with the modified aircraft transponder of “mode 1090 ES” (extended squitter), which supports a periodical transmission of digital messages. A digital message includes an airplane identification code and its position. A modified transponder is one of the ways of ADS-B implementation in aviation. According to ADS-B, each user of airspace should measure its location with a certain level of accuracy and automatically share it in a broadcast mode with other users and air navigation service providers. ADS-B implementation stimulated a wide usage of digital data receivers on board of airplanes. As a result, air traffic can be displayed on EFIS in order to increase the situational awareness of pilots. In the near future, TCAS will use ADS-B data to reduce the workload on the aircraft transponders (De and Sahu, 2018).

Some general aviation airplanes may use a passive surveillance system in contrast to active surveillance in TCAS I. Portable collision avoidance system (PCAS) utilizes a passive surveillance approach. PCAS is based on the receiving both signals from ground SSR and aircraft replies to measure distances to airspace users around. PCAS antenna system uses a combination of signal amplitude and phase cancellation to detect direction data to other traffic. A relative height between the airplanes is obtained by comparison of their own barometric height with the height obtained from aircraft transponder messages. PCAS is implemented as a single block with a built-in display of air traffic, which provides a pilot with information about air traffic around them using visual and audio warnings about violation of separation minimums. Nowadays, ADS-B has gradually excluded PCAS from the market; however, a large number of general aviation airplanes is still equipped with PCAS.

Terrain Avoidance and Warning System

Airplane operation at low altitude always presents a severe risk to flight safety. Early detection and avoidance of conflict situations with the relief and artificial constructions is provided by terrain avoidance and warning system (TAWS) on board of the airplane (Breen, 1999).

TAWS implements two fundamentally different approaches for early detection of dangerous situations. At the first approach, the near-miss analysis compares flight parameters with their limits. Deviation of flight parameters out of required limits can lead to the conflict with a terrain. Boundary values of several parameters, considered simultaneously, define an area of permissible values. Each of the dangerous states corresponds to a certain area. Parameter deviations outside their limits initiate warnings to the pilots. In particular, the following pairs of parameters are analyzed: height above ground level (AGL) and vertical speed, AGL and high rate of descent, AGL and deviation from a glideslope (Fig. 3). All of these parameters identify airplane location close to the terrain and are used to generate oral and visual warnings for a pilot.

Another approach to determine potentially dangerous situations is done by the forward looking terrain alerts (FLTA). In this approach, TAWS uses airplane position and velocity to predict further flight trajectory to compare it with a global digital elevation model. Some TAWS can be equipped with a database of artificial elements to generate obstacle warnings. As GNSS is used as a common positioning system, its accuracy and resolution of the digital elevation model determine the performance of near-miss analysis at FLTA. The indication of the TAWS system represents the relative heights and dangerous elements of the relief to the pilot, according to the level of danger (Fig. 4).

There are different types of TAWS according to aircraft type. Also, there is a helicopter version of TAWS due to performance features of a controlled flight into terrain (Anderson et al., 2011).

In the general case, the majority of onboard systems are critical and the fault of a particular one can be considered as an incident that could lead to a catastrophe. To enhance system reliability, each of the important systems is duplicated. In particular, the digital data buses that ensure the data exchange between the airplane systems can be duplicated up to 5 times to reduce the number of failures. Near-miss analysis on board of an airplane is carried out at different levels to ensure the necessary safety conditions of flight. In particular, each of avionics systems has its own built-in health monitoring function and initiates the performance self-test at the start of an operation. A system provides a discrete signal transmission about the system fault to inform all other equipment in case of failure detection. In addition, each measured value is analyzed for outliers or complete inadequacy of the observed physical processes. In case of significant outliers in the sensor measurements, the built-in control system generates a discrete signal of failure, which is automatically reported to other onboard equipment for excluding faulty measurements from the computations. In order to fulfill gaps in measured data, different data recovery algorithms are used on board of a modern airplane.

Figure 3 TAWS.

Figure 4 Visual warning about dangerous terrain in front of an airplane from TAWS on board of An148.

Flight data recording system provides registration of the flight data and the measurements of onboard sensors. The set of data is available for analysis during airplane maintenance. Software for data processing supports a near-miss analysis by recorded data, which includes equipment faults detection, risks estimation, and detection of avionics that may cause a threat due to a high risk of failure. The wide use of computerized maintenance system of onboard equipment monitoring significantly increases the safety of air transportation.

An airplane operation is controlled from the ground by the ATC unit. The ATC services support air traffic with the aim of the planning of the nonconflict airplanes flow within the controlled airspace. Similar to onboard TCAS, the algorithms of early collision detection are used in ATC unit. The functionality of the ATC unit also includes detection of airplanes deviations from the pre-planned trajectory and separation minimum. Data from various sensors about air traffic are compared with scheduled flight plan databases in ground incident detection systems.

In the framework of the controlled air traffic, an ATC must provide a conflict-free airplane flow. Thus, the TCAS onboard system plays a supporting role. For example, the appearance of resolution advisory in TCAS II may indicate an incorrect ATC clearance or pilot mistake.

Biography

Ivan Ostroumov has been a faculty of Air Navigation Systems Department of the National Aviation University of Ukraine since September 2007. He obtained his PhD degree of Engineering in Navigation and Traffic Control in 2009 from National Aviation University of Ukraine. Since then, he has been a research scientist and associated professor for National Aviation University. Since 2016, he has also served as navigation instructor at "Aviation Company Ukrainian Helicopters." In 2017/2018, he was a Fulbright scholar in the School of Aeronautics and Astronautics at Purdue. Also, he took part in several projects, including Supporting SESAR on GNSS Vulnerability Assessment by performing Space Weather Analysis (Navigation department, EUROCONTROL, Brussel) and e-learning course development (Institute of Air Navigation Services, EUROCONTROL, Luxembourg). His research theme is advanced methods for Alternative Positioning, Navigation, and Timing. His current research projects include Methods and Algorithms of positioning by multiple navigational aids, Availability and Accuracy estimation of navigation.

Nataliia Kuzmenko is a senior researcher of the National Aviation University of Ukraine. She obtained her PhD degree of Engineering in Navigation and Traffic Control in 2017 from the National Aviation University of Ukraine. She is a certified aviation security instructor by ICAO (ASTP/Basic, ASTP/Instructors). She has had a traineeship in Tool Development for support to CAA/NSA at Regulatory Division within the Directorate Single Sky (Eurocontrol, Brussels). Her current research projects include aviation safety, collision detection and avoidance, artificial intelligence, Remotely Piloted Aerial Systems, video stream object detection and recognition, kernel density estimation, and neural networks.

International Differences

Most road traffic deaths and injuries occur in the low- and middle-income countries which are experiencing rapid levels of motorization. The death rates in low-income countries are roughly 3 times higher compared to high-income countries (the average rate in low-income countries is 27.5 deaths per 100,000 population compared to 8.3 per 100,000 population in high-income countries). Low-income countries account for around 1% of motor vehicles but 13% of traffic deaths ([World Health Organisation, 2018, 2018](#)) ([Fig. 1](#)).

The rates of road traffic deaths are highest in Africa and Southeast Asia (26.6 and 20.7 deaths per 100,000 people, respectively). In the lowest income countries in Africa, the rate is 29.3 ([Fig. 2](#)).

Within the overall global figures, vulnerable road users are particularly overrepresented in the fatality figures compared to their use of the roads—54% involve pedestrians, cyclists, and motorcycle users. [Fig. 3](#) shows the variability between different WHO regions, showing some regions, especially Africa, having very high levels of pedestrian deaths compared to elsewhere. Also of note is the high levels of motorcycle deaths in Southeast Asia.

A further aspect that varies considerably between countries is the availability and quality of postcrash care—the proportion dying before reaching hospital is over twice that in low-income countries compared to high-income countries.

Ameliorating road safety requires new implementation of context-specific solutions. Road safety literature provides strong evidence that the distribution of road traffic fatalities varies dramatically across different parts of the world. This strongly suggests that context-specific and effective prevention strategies that protect the particular at-risk road user groups should be carefully investigated ([Naci et al., 2009](#)) and that what works or is normal in one place may not work elsewhere.

Within Country Differences—Differences Between Groups

People living in disadvantaged areas tend to live in areas where they are more exposed to traffic risk and are at greater risk of injury and death. Use of motorized transport such as cars provides a greater level of protection from injury than users less protected such as pedestrians, cyclists, and motorcyclists. People living in more deprived neighborhoods have been shown to be more likely to be killed or injured as road users (see [Ward et al., 2007](#), [Christie et al., 2007](#), or [Muir, 2013](#)). The variation in risk between different socioeconomic groups is particularly pronounced for certain road user groups such as pedestrians and especially so for children and young people ([Lucas et al., 2019](#)).

More deprived areas of cities tend to be more hazardous in terms of traffic with more through traffic, often taking shortcuts through residential roads and along roads not designed to cope with traffic volumes experienced, greater issues from things such as on-street parking, and often more complicated crossing environments. Such areas often contain little in the way of green space and children's outdoor play is more likely to occur in the street environment ([Morency et al., 2012](#)). There is some evidence that targeted improvement schemes, such as traffic calming, applied in such areas can help to mitigate socioeconomic differentials in injury rates ([Steinbach et al., 2011](#)).

The Future—Impact of Increasing Autonomy

Various future technological developments are being considered which will have an impact on road safety. Potentially the most impactful of these is the proposed developments in autonomy and independent control of vehicles which ultimately could lead to completely self-driving vehicles. The last decade or so has already seen increasing levels of technological sophistication in this area in motor vehicles, such as parking aids and cruise control systems keeping safe distance to the vehicle in front, which are now fairly standard in new vehicles, as well as improvements to safety aids and other driver support systems in vehicles. A future where autonomous vehicles are the norm could substantially change safety, removing much or all of the control from humans and making

*Income levels are based on 2017 World Bank classifications.

Figure 1 Proportion of population, road traffic deaths, and vehicles by income level 2016. Source: *World Health Organisation, 2018*.

Figure 2 Rates of road traffic death per 100,000 population by WHO regions 2013, 2016. Source: *World Health Organisation, 2018*.

movement in cars and other motor vehicles considerably safer than is currently the case. However, it is not yet clear whether such safety gains will be equitably achieved amongst different road user groups. For example, how will non-motor vehicle users such as pedestrians and cyclists be affected by such a future? Arguably, they may also see safety improvements as motor vehicles will likely be more efficient at stopping or avoiding potential crash situations, but will the safety gains be as high for the nonmotorized road users as for their motorized counterparts? In part this might depend on the detail of the vehicle programming, in particular the oft-considered situations where a vehicle has a difficult choice to make between two negative outcomes in a crash situation—for example, whether to hit another car or to hit a pedestrian in the road. It is possible that inequality might even be consciously or unconsciously built into the vehicle control systems themselves.

Such new technologies are also likely to take a considerable period of time before they trickle down to all vehicles in all countries, perhaps appearing last in the lowest income countries of the world where only a very small percentage of the people will afford them. This will have the effect of increasing existing inequalities in safety between the highest and lowest income countries.

In summary, there currently exist major differences in safety between different groups of society—the differences are principally between those who have the means to afford to use safer modes of travel, such as cars, where the occupants are well protected in the event of a crash and those who are more vulnerable to injury such as walkers and cyclists. There are also differences according to the level of wealth of countries and regions and their ability to provide safe environments in which travel can take place, appropriate training and education programs to enhance user abilities and perceptions of safety, and safety standards and quality of vehicles available. However, even among countries with similar per capita GDP, some provide better safety than others do. For example,

Figure 3 Distribution of deaths by road user type by WHO region. Source: *World Health Organisation, 2018*.

Sweden in 2017 had a fatality rate of 2.54 per 100,000 people—and the United Kingdom had a similar rate—whereas the United States had a rate more than 4 times higher at 11.40 per 100,000 people even though a lower percentage of people walk and ride bicycles in the United States. A part of the difference is explained by people in Europe making more trips by bus and train, which are even safer modes than the car, so people travel fewer miles by car. Another difference is the distribution of income and education level. Parts of the United States have fatality rates similar to European countries and other parts similar to low-income countries. The state with the highest education level, Massachusetts, had a per capita fatality rate of 5.1 in 2017, whereas Mississippi had a rate of 23.1 per 100,000 people. And, 42% of people in Massachusetts had a Bachelor's degree or higher in 2017, whereas only 21% did in Mississippi. In 2017, Massachusetts had a per capita personal income of almost exactly double that of Mississippi. In addition, even within these states, local traffic safety seems to vary with income and education level.

Introduction

Lighting is a critical element of the roadway visibility system. After an introduction to driver and pedestrian visual performance, this chapter discusses the design and implementation of roadway lighting systems and requirements for vehicle lighting systems, including their interactions with other visibility elements along the roadway. The chapter concludes with a brief discussion of application issues that can impact lighting practices.

Visibility

Visual Performance

The primary purpose of lighting in the roadway environment is to aid vision. An understanding of visual tasks and the factors that affect visual performance can aid in providing the appropriate level of lighting for those tasks. Visual performance, the speed, and accuracy with which a visual task can be performed is affected by several factors (Rea and Ouellette, 1991), including contrast, size, and duration.

Contrast (Fig. 1) refers to the luminance difference between the critical detail of a task and its background, for example, the clothing worn by a pedestrian against the paved surface of the roadway behind the pedestrian. A reading task such as white letters on a black sign background would have a high contrast, whereas a dark-colored animal viewed against a dark background of foliage could have a low contrast, approaching zero. As the contrast of a task increases, visual performance also increases. Once contrast is sufficiently high, further increases in contrast will have little effect on visual performance.

The size of the visual task is also important. A task with an infinitesimally small size will be invisible, with visibility increasing as size increases. As with contrast, once the size is sufficiently large, making it larger will not increase visual performance very much. For example, visual performance while reading 6-point type might be significantly better than visual performance reading 4-point type, but visual performance while reading 18-point type would only be marginally better than visual performance reading 12-point type.

The duration a visual task is presented also affects visual performance. For visual tasks, which are visible for only very brief periods of time (less than 0.1 s), the intensity and duration are traded off, such that a signal which appears for half the duration as a second signal would need to have twice the intensity to be as visible as the second signal. For presentation durations longer than 0.1 s, the duration of the visual task is much less important.

For a visual task with a specific contrast, size, and duration, lighting directly affects another factor, which helps determine the overall visual performance. The background luminance is affected by the illuminance falling on the surface surrounding the object and by the reflectance of that surface. Holding contrast, size, and duration constant, the higher the background luminance is, the better visual performance will be. Similarly, visual acuity (ability to distinguish detail of the smallest objects that can be seen) improves with increasing light levels. In addition, both speed and accuracy of visual processing improves with higher light levels. Dark surfaces, such as asphalt, will have a lower luminance than lighter surfaces, such as concrete, even for the same illuminance falling on them, because the reflectance of asphalt is lower than that of concrete.

Although the performance of a visual task improves with higher light levels, the rate of improvement decreases when the light level is high. This “plateau” effect is inherent to most visual tasks encountered at work or at home when objects in the field of

Figure 1 Illustration of contrast changes; contrast is lowest for the objects near the center.

view are well above the visual threshold. For very small, low contrast visual tasks, however, the light level will have a relatively larger impact on visual performance. The age of the occupant should also be considered when planning a lighting system. The amount of light reaching the retina of a 50-year-old person is approximately 50% of that for a 20-year-old (Rea, 2000) because the lens of the eye yellows and thickens during aging, and because the pupil of the eye tends to decrease in size as a function of age.

Glare

Although lighting is usually considered to be beneficial for visibility, excessive light can reduce visual performance by creating disability glare, which is the reduction in contrast caused by a bright light in the field of view that results in scattered light inside the eye. This scattered light creates a veiling luminance analogous to looking through a veil or haze (Fry, 1954).

Bright light sources can also cause discomfort glare, which is the annoying or even painful sensation created by the offending source. Mechanisms for discomfort glare are not well understood but differ from those for disability glare. Two lights that reduce visibility equally may be perceived as unequally uncomfortable; lights with substantial short-wavelength (“blue”) spectral content tend to be rated uncomfortable compared to “yellowish” lights (Bullough, 2009). Nonetheless, disability and discomfort glare often occur simultaneously in the nighttime lighted environment.

Lighting Technologies

Several types of light sources, or lamps, are commonly used in transportation lighting systems, consult Rea (2000) and the National Lighting Product Information Program (www.lrc.rpi.edu/programs/nlpip) for detailed technical information on many different electric light sources. Important light source performance characteristics include luminous efficacy (lm/W), rated life, color rendering characteristics, and lumen maintenance (defined as the percentage of light output that can be reasonably expected from a lamp after it has operated for approximately half of its rated life).

Light-emitting diode (LED) sources are becoming the primary light source used in transportation lighting applications. They are beginning to rapidly replace halogen, filament-based sources in vehicle lighting, and high-intensity discharge lamps in roadway illumination systems.

Light-emitting Diodes

First invented in the 1960s, LEDs have increased in efficacy, in light output, and in the range of available colors. The development of blue LEDs that emit short-wavelength light has permitting the subsequent creation of white-light LED systems in two ways: by combining red, green, and blue LEDs to create white light, and by using phosphors together with blue LEDs that convert some of the blue light into yellow light, resulting in a mixture that is perceived as white light. Newer packages for LEDs have been developed in addition to the familiar 5-mm diameter epoxy capsule LED packages used for indicator lights, which produce greater light output and wider distributions than LEDs had previously been able to exhibit. Many LED luminaires use arrays of LED packages to create the necessary distribution (Fig. 2). Some LED luminaire packages contain metal fins or slugs as heat sinks to help dissipate internal temperatures. Increased temperature inside the LED reduces its light output and over the long term, can shorten the useful life of the source. Color rendering depends upon the combination of phosphors used to generate white light, and luminous efficacies presently range from 30 to more than 60 lumens (lm) per watt (W).

While LEDs have very long operating lives, typically more than 50,000 h without failing, they do exhibit gradual reductions in light output over time. White LED indicator type packages with no heat sinking have been shown to reach half their initial light output within 10,000 h. Improved packages have exhibited much improved lumen maintenance characteristics.

Figure 2 Photograph of LED luminaires.

Vehicle Lighting

Forward Lighting

The majority of roads are not lighted; therefore, vehicle forward lighting systems are necessary for safe nighttime travel. There are two primary types of beam pattern, or distributions of luminous intensity, permissible for vehicle headlamps, known as the high beam (or driving beam) and the low beam (or passing beam).

Fig. 3 illustrates a representative beam pattern for a low beam headlamp, projected onto a vertical wall. In order to control glare, many low beam patterns exhibit relatively sharp vertical cutoff angles, above which there is relatively little light. The sharp cutoff originated with headlamps based on United Nations regulations for vehicle lighting, and it permits visual aiming of headlamps by adjusting the vertical tilt. Most headlamps in North America have followed suit since the early 2000s, using sharp vertical cutoffs in the beam pattern ([Schoettle et al., 2008](#)). For example, for the pattern in **Fig. 3**, the location of the right-side cutoff is at 0° , or in other words, at the same height as the headlamp. The cutoff on the left side, corresponding to likely locations of oncoming traffic, is often lower than the right-side cutoff to reduce glare.

The sharp cutoff of low beam headlamps can restrict the forward visibility of drivers, even on flat, straight roads, driving speeds in excess of 55–65 km/h will make it impossible for a driver to detect and stop in time to see some potential hazards ([Andre and Owens, 2001](#)). The use of high beams is warranted for these situations (except when approaching traffic is within about 150 m), but drivers almost universally underuse their high-beam headlamps ([Sullivan et al., 2004](#)).

The sharp vertical cutoff of low beam headlamps makes vertical aim critical in the performance of these lighting systems. Recent measurements of vehicles ([Skinner et al., 2010](#)) have found that the majority of vehicles measured had at least one misaimed headlamp. Upward misaim is probably the largest contributor to disability and discomfort glare from headlamps, and downward misaim can severely restrict forward visibility, because of the sharp vertical cutoff. In the United States, most states do not include

Figure 3 Photograph of the beam pattern from a typical low beam headlamp projected onto a wall.

precise checks of headlamp aim for vehicle safety inspections; a few states and many other countries do include headlamp aim in the inspection process.

High-beam headlamps are permitted by United Nations and North American regulations not only to have higher luminous intensities than low beams, but to produce light above the typical vertical cutoff location of low beam headlamps. This, of course, increases the range of visibility for the driver, and also increases the likelihood of creating disturbing glare to oncoming and preceding drivers, and may explain their underuse.

Forward lighting systems that change dynamically in response to specific driving conditions are now beginning to show promise for changing the fixed, high/low beam pattern paradigm for headlamps. One recent and dramatic development in vehicle forward lighting is the introduction of adaptive driving beam (ADB) headlamps. ADB systems are essentially matrix configurations usually using LED sources where each source produces a specific angular portion of the headlamp beam pattern. Using cameras and other sensors, the ADB systems can reliably detect and identify headlamps from oncoming vehicles and tail lamps of preceding vehicles, and will dim the intensity from the ADB system only in those directions. This has the effect of reducing glare for other drivers while maximizing visibility for the driver with the ADB system. ADB systems are legal in most countries, which use the United Nations vehicle lighting regulations. Studies have demonstrated these benefits empirically ([Bullough et al., 2016](#)) and the US Department of Transportation is considering how to permit these systems on American roads, as currently (in October, 2019), only fixed low-beam- and high-beam headlamps are permitted.

Roadway Lighting

In this section, the safety impacts of roadway lighting, the equipment used for roadway lighting, and some of the design criteria for roadway lighting are described.

Lighting and Safety

Almost all transportation agencies recognize that roadway lighting reduces nighttime crashes, and most empirical evidence is consistent with this notion. Measuring the safety impacts of roadway lighting is difficult because crashes are relatively rare, random events that require long periods of time to measure statistically reliable effects. Many factors may change along a roadway (daily traffic, road geometry, number of lanes, to name a few), so before/after studies of roadway lighting can be confounded by different periods of time. Studies comparing different locations with and without roadway lighting require very careful selection of sites to avoid confounding (a location near a shopping center would be very different with respect to crashes than an isolated rural location).

A nighttime crash reduction factor of about 30% was found in a review of more than 60 studies of roadway lighting ([Commission Internationale de l'Éclairage, 1992](#)). Although this single nighttime crash reduction factor of 30% is often used by transportation agencies to predict the benefits of roadway lighting, it is only reasonable to suppose that roadway lighting does not have the same benefit in all situations. Indeed, careful review of the literature has shown that in locations with complex roadway geometries, high potential for conflicts, or large pedestrian populations, the nighttime crash reduction factor associated with lighting appears to be larger than along straight, access-controlled highways with little to no pedestrians. Pedestrians appear to be particularly vulnerable during nighttime conditions, and reduced visibility is a likely contributor to this vulnerability.

Despite controlling for many operational and geometric factors that is inherent in the use of daytime crashes to serve as a type of control condition, observational studies using with/without or before/after methodologies can still contain biases. In part this is because roadway lighting is not assigned randomly to various roadway locations. Instead, if lighting is installed along an existing roadway, this might have been done in response to a higher than average observed number of crashes within a relatively short period of time of a few years. If the increase was spurious, it is possible that the number of crashes could undergo regression to the mean, and exhibit a relatively lower number of crashes simply because a roadway cannot experience an above-average number of crashes every year. Another explanation of bias might be that roadway lighting is often only one of many safety-related measures that might be installed along a roadway, also including improved lane markings, medians, turn lanes, or traffic signals, and these could be partially responsible, along with lighting, for any safety improvement.

A recent study to attempt to reduce such potential sources of bias ([Bullough et al., 2013](#)) used multiple nonlinear regression modeling that included not only the presence of lighting but the type of location (i.e., urban or rural), posted speed limit, percentage of heavy trucks, average daily traffic, number and width of lanes, presence of signalization and other geometric, and demographic variables in order to isolate the safety effect (if any) associated only with roadway lighting. The results were consistent with other studies ([Commission Internationale de l'Éclairage, 1992](#)) in that there was generally a reduction in nighttime crashes associated with roadway lighting, but the magnitude of the effects were smaller, as might be expected. The nighttime crash reduction factor associated with roadway lighting was closer to 10% for intersections, and smaller for highway segments with no intersections or interchanges, not 30% as commonly used by many transportation agencies.

The discussion of visual performance earlier in this chapter should reinforce the notion that improvements in visibility, the logical mechanism accounting for safety improvements associated with lighting, will depend upon the light level and other factors associated with a specific lighting configuration. A systematic examination of the visual performance benefits of roadway lighting of different light levels and spatial extents (i.e., one or two light poles at an intersection, versus a continuously lighted

Figure 4 Agreement that outdoor lighting at night leads to perceptions of safety as a function of average illuminance on the pavement.

roadway approaching an intersection) used in conjunction with vehicle headlamps, and in locations varying in vehicle speeds, amount of ambient light from commercial properties, and for drivers of varying ages was conducted (Bullough and Rea, 2011) in conjunction with the statistical study of lighting and crashes by Bullough et al. (2013). The results of both studies yielded converging results.

For example, the benefit of roadway lighting at rural intersections was found to be negligible even though such areas are inherently dark at night, and lighting would be expected to improve visual performance, particularly when driving with low beam headlamps at speeds greater than 65 km/h, which are common on many rural highways. There were only modest visual performance improvements from “point” lighting consisting of only one or two poles at the intersection, especially for drivers along the secondary road of such an intersection. Continuous lighting of the rural highway, by comparison, would provide substantial improvement over no lighting or even “point” lighting, but is rarely used in practice (Bullough and Rea, 2011). Given these findings, drivers might be better served by lighting the approaching legs of a rural intersection and not only the immediate conflict area. It is unclear whether the practice of “beacon” lighting, where a low-wattage luminaire is mounted at a rural intersection along an otherwise unlighted road to provide an indication about the presence of the intersection, is beneficial in terms of crash reductions.

Roadway lighting can, however, improve subjective impressions of the safety of a location (Leslie and Rodgers, 1996). Surveys of exterior lighting in major urban areas as well as suburban locations found perceptions of safety and security to be positive when the average illuminance exceeded 10 lux (Fig. 4); higher light levels were not judged as feeling particularly safer.

Roadway Lighting Practices

For the most part, roadway lighting systems consist of luminaires mounted to poles, usually with individual controls consisting mainly of photocells. Poles are most commonly aluminum, steel, or wood. In many locations, existing utility poles are used to support roadway luminaires (in such cases, the lighting system is likely to be sub-optimal because utility pole locations are not determined by lighting or visibility considerations). If dedicated lighting poles are used, the utilities may be buried underground to improve the visual appearance. Cost may determine whether poles must be mounted along a single side of the road, or along both sides in an opposite or staggered arrangement.

In pedestrian crosswalks, one approach to lighting that has been investigated is the use of bollard-level lighting systems (Fig. 5) along the edges of the crosswalk (Bullough and Skinner, 2017). These systems provide illumination on the vertical surfaces of pedestrians crossing the street, in many cases making them more visible to oncoming drivers than overhead roadway lighting.

As mentioned previously, the most common control system for roadway lighting is a photocell mounted to an individual luminaire, which will switch the luminaire on and off at a specified ambient light level. Some systems will use centralized control via a single photocell or time clocks. Technological innovations are making centralized control systems attractive because these systems can also monitor the performance of individual luminaires and alert the system operator when a lamp or ballast failure has occurred or is close to occurring.

Figure 5 Photograph of bollard-level crosswalk lighting.

Standards such as those published by the [Commission Internationale de l'Éclairage \(2010\)](#) and the [Illuminating Engineering Society \(2018\)](#) are the basis for the design of continuous roadway lighting systems. These standards provide different light level recommendations as well as recommendations for uniformity (expressed as the ratio between the average and minimum light levels along the road) and the amount of disability glare that lighting systems should produce. These recommendations for uniformity and glare directly impact the spacing between poles for continuous roadway lighting. In general, busier roads and those with greater pedestrian conflict are expected to be lighted to higher light levels. The uniformity and glare recommendations are designed to help ensure that pole spacing between luminaires does not result in excessively dark portions of the illuminated roadway.

Just as vehicle lighting is beginning to implement adaptive control schemes, adaptive roadway lighting is also becoming more prevalent, based on the notion that very late in the night, there is likely to be much lower traffic and pedestrian use along many roads than there would be earlier in the evening. Accordingly, light levels may be reduced during these periods of reduced activity in order to save energy and minimize factors such as light trespass (light falling onto adjacent properties where it may be unwanted) and sky glow (brightening of the night sky making stars less visible). Such environmental impacts of roadway lighting are becoming more important to the general public.

Introduction

Traffic safety is considered one of the most important areas in the transportation field. With consistent efforts of transportation engineers and researchers, both fatalities and fatality rates from traffic collisions have steadily declined between 2003 and 2011 in the United States. Nevertheless, traffic fatalities and fatality rates started to rise since 2012. And, as seen in an international perspective, the United States has gone from being among the top countries in traffic safety on a per capita as well as per-mile basis 40 years ago to nowadays being below many if not almost all other industrialized countries. In the United Kingdom along with Germany and France, traffic fatalities have been continuously decreasing since 2000.

Many researchers have conducted studies to reveal hot spots for traffic crashes and identify significant contributing factors to traffic crashes. In order to identify traffic crash prone locations or finding contributing factors for repeated traffic crash occurrence, specific traffic crash locations would be aggregated into segments, intersections, zones, etc. In general, traffic safety analysis can be classified into two categories: microscopic and macroscopic analyses. The microscopic safety analysis focuses on roadway entities such as segments, intersections, corridors, ramps, etc. The microscopic safety analysis aims at identifying contributing factors to traffic crashes from roadway geometric designs and traffic features of roadway entities, and providing specific engineering countermeasures to alleviate traffic safety problems. On the other hand, the macroscopic safety analysis concentrates on zonal-based traffic crashes with demographic, socioeconomic, land use, and zonal level traffic/roadway characteristics. Compared to the microscopic level study, macroscopic analysis provides a broad-spectrum perspective, and also it suggests long-term policy-based countermeasures such as enactments of traffic laws/rules, police enforcement, education, safety campaigns, and area-wide engineering solutions.

In the United States, Moving Ahead for Progress in the 21st Century (MAP-21) Act and Fixing America's Surface Transportation (FAST) Act proposed the requirement to incorporate traffic safety into the long-term transportation planning process. Therefore,

transportation engineers need to exert more effort to improve traffic safety and solve safety problems along with long-term transportation planning. This is the main reason that the macroscopic safety studies have become more popular during the last decade. The objective of this article is to comprehensively review and summarize macroscopic safety studies and provide researchers and practitioners with a better understanding and discuss recent trends in traffic safety research studies at the macroscopic level. This article comprises seven sections: geographic units, methodologies and issues, macroscopic contributing factors to traffic crashes, recent issues and topics, and summary and conclusions. Reference and further reading lists are provided at the end of this article.

Geographic Units

Macroscopic traffic safety studies require base geographic units. The number of crashes is aggregated into each spatial unit and the relationship between the aggregated crash counts (or crash rates) and zonal explanatory variables is explored. In the United States, which will be the focus of this description, geographic units include census-based units such as census blocks (CBs), census block groups (BGs), or census tracts (CTs). Traffic-based units such as traffic analysis zones (TAZs) or political boundary units such as counties have been used as base spatial units in some macroscopic safety studies.

Census-Based Units

CBs are the smallest geographic units used by the United States Census Bureau (USCB) for the collection and tabulation of decennial census data. However, detailed information is not available based on CBs due to confidentiality requirement. Generally, CBs are very small, especially in the urban areas. On average there are 85 people in one CB. Due to the privacy reasons, detailed information is not allowed for these small units, so CBs have not been used in macroscopic traffic safety studies. Census BGs are the next level above CBs. BGs are combinations of CBs. Each BG contains 39 CBs on average. Population in a BG ranges between 600 and 3000 people. Some macroscopic traffic safety studies adopted BGs as a base geographic unit. CTs are designed to maintain homogenous socioeconomic status in a zone. CTs are statistical subdivisions of a county that may include 2500–8000 people. Several researchers have analyzed macroscopic traffic safety based on CTs. Moreover, Census Wards, a census unit used in the United Kingdom, have been used in some macroscopic safety studies. **Fig. 1** compares CBs, BGs, and CTs in Downtown Orlando. As shown in **Fig. 1**, CBs are the smallest, whereas BGs and CTs are much larger than CBs.

Traffic-Based Units

Traffic Analysis Zones

TAZs are special-purpose geographic entities delineated by state and local transportation officials for tabulating traffic-related data, especially journey-to-work and place-of-work statistics. Since TAZs are the only traffic-related zone system, TAZs have been the most popular in the macroscopic safety literature.

Traffic Analysis Districts

Traffic analysis districts (TADs) are new, higher-level geographic entity for traffic analysis. TADs are created by aggregating existing TAZs. TADs may cross county boundaries, but they must nest within metropolitan planning organizations. Nevertheless, very few macroscopic safety studies have used TADs as a geographic unit in traffic safety analysis till now. **Fig. 2** compares TAZs and TADs in Orange County in Florida.

Traffic Safety Analysis Zones

Recently some researchers developed geographic units exclusively for traffic safety, called traffic safety analysis zones (TSAZs). TSAZs were developed using regionalization methods and estimated macroscopic safety models based on TSAZs. The development of TSAZs will be explained in detail later.

Political Boundary Units

For higher levels of macroscopic analysis, counties, states, or even nations are used as spatial units. One of the issues to analyze crashes using multinational data was the inconsistency in definition, quality, and availability of data.

Postal Units (ZIP Code)

ZIP code is a system of postal codes made and used by the United States Postal Service since 1963. As a matter of fact, ZIP codes are not a geographic unit but a collection of mail delivery routes. US census created ZIP code tabulation areas (ZCTAs), which are generalized areal representations of ZIP code service areas. ZCTA-based data are also provided from the USCB. Many studies using ZIP codes have been conducted. ZIP codes are mostly used for the residence information, instead of the crash location. This is because the residence information is only provided as a ZIP code in most cases. Many researchers have focused only on road users

Figure 1 Census-based geographic units in Downtown Orlando, Florida.

who are involved in fatal crashes since Fatality Analysis Reporting System (FARS) offers ZIP codes of drivers involved in fatal crashes. Thus, ZIP code-based studies using FARS ZIP code data only focus on fatal crashes.

Developing New Geographic Units for Macroscopic Safety Analysis

As mentioned previously, TAZs have been most widely used in macroscopic safety studies. Nevertheless, there are possible limitations of TAZs for macroscopic safety analysis due to the zoning criteria. The general zoning criteria for TAZs are as follows (Baass, 1980):

1. Homogeneous socioeconomic characteristics for each zone's population.
2. Minimizing the number of intrazonal trips.
3. Recognizing physical, political, and historical boundaries.
4. Generating only connected zones and avoiding zones that are completely contained within another zone.
5. Devising a zonal system in which the number of households, population, area, or trips generated and attracted are nearly equal in each zone.
6. Basing zonal boundaries on census zones.

Criteria (1), (4), (5), and (6) are also sensible for the macroscopic safety modeling. Nevertheless, possible limitation of TAZs for the crash analysis arise from criteria (2) and (3). Basically, TAZs were designed to find out origin-destination pairs of trips generated from each zone. Thus, transportation planners need to minimize trips that start and end in the same zone. It is thought that minimizing intrazonal trips ends up with the small size of TAZs. On the other hand, traffic safety analysts need to analyze traffic crashes that occur inside the zone, so they are able to relate zonal characteristics with traffic crash patterns of the zone. Therefore, it is possible that TAZs are too small to analyze traffic crashes at the macroscopic level. Moreover, the small size of zones makes many zones with zero crash frequency, especially for rarely occurring crashes such as severe, fatal, or pedestrian crashes. Criterion (3) indicates that TAZs are

Figure 2 Traffic-based geographic units in Orange County, Florida.

usually divided based on physical boundaries, mostly arterial roadways. Considering that many of the crashes occur on arterial roads, between zones, inaccurate results will be made from relating traffic crashes on the boundary of the zone to only the characteristics of one zone. A simple way to overcome these two issues from using TAZs for the safety analysis is to aggregate TAZs into sufficiently large and homogenous traffic crash, sociodemographic, or traffic patterns (TSAZs). This process is called regionalization.

Methodologies and Issues

Statistical Modeling Methods

A wide array of statistical techniques for macroscopic safety analysis has been utilized. The statistical methods for macroscopic safety analysis are not very different from those for microscopic safety analysis. In this section, statistical models that are widely used for macroscopic safety models, including Poisson, negative binomial (NB), Poisson-lognormal, random effects, and multivariate models will be briefly addressed.

Since crash frequency data are nonnegative integers, the application of ordinary least squares regression is obviously not suitable. For crash count analyses, Poisson regression models have been used for several decades.

The equation of Poisson model is as follows:

$$P(y_i) = \exp \frac{(\lambda_i) \lambda_i^{y_i}}{y_i!} \quad (1)$$

where $P(y_i)$ is the probability of roadway entity i having y_i crashes per time period and λ_i is the Poisson parameter for the roadway entity (segment, intersection, etc.) i , which is equal to roadway entity i 's expected number of crashes per year, $E[y_i]$. Poisson regression models are estimated by specifying the Poisson parameter λ_i (the expected number of crashes per period) as a function of explanatory variables. Broadly used functional form for the Poisson regression is:

$$\lambda_i = \exp(\beta X_i) \quad (2)$$

where X_i is a vector of explanatory variables and β is a vector of estimable parameters.

The Poisson model is the most basic and also easy to estimate, but it cannot handle over-dispersion and under-dispersion. Over-dispersion is one characteristic of crash count data, which is that the variance exceeds the mean of the crash frequencies. Over-dispersion can violate the assumption of the equal mean-variance. Under-dispersion is that the mean of the crash counts is greater than the variance. Incorrect parameter is estimated in the existence of under-dispersed data. Moreover, the Poisson model is largely affected by low sample-mean and small sample size bias.

NB, or Poisson-gamma model, is an extension of the Poisson model to overcome the over-dispersion problem. NB model assumes that the Poisson parameter follows a gamma probability distribution. The NB model is derived by manipulating the relationship between the mean and the variance. The equation of NB model is as follow:

$$\lambda_i = \exp(\beta X_i + \varepsilon_i) \quad (3)$$

where i is each observation, $\exp(\varepsilon_i)$ is a gamma-distributed error term with mean 1 and variance α . The addition of variance term α allows the variance to differ from the mean as:

$$\text{VAR}[y_i] = E[y_i][1 + \alpha E[y_i]] = E[y_i] + \alpha E[y_i]^2 \quad (4)$$

Both the Poisson and NB regression models had been widely used since they can well represent crash count data. Additionally, the NB model performs better than Poisson regression model, especially when over-dispersion exists. Although NB model still cannot handle under-dispersion problem and it is also affected by low sample-mean and sample size bias, NB models are the most frequently used models in crash frequency.

In recent years, several traffic crash studies have been conducted using Poisson-lognormal models. The Poisson-lognormal model was suggested as an alternative to the NB model for crash count data. The Poisson-lognormal model is similar to the NB model, but the $\exp(\varepsilon_i)$ is a lognormal rather than gamma-distributed. Admittedly, the Poisson-lognormal can provide more flexibility compared to the NB model; it has two disadvantages: (1) model estimation is more complicated, and (2) still negatively affected by small sample sizes and low sample-mean values.

The correlation among observations could arise from spatial and/or temporal considerations. Random-effects model and fixed-effects models can be considered to account for such correlation. Random-effects model is considered where the common unobserved effects are assumed to be distributed over the spatial/temporal units according to some distribution and shared unobserved effects are assumed to be uncorrelated with explanatory variables. Fixed-effects models are considered where common unobserved effects are accounted for by indicator variables and shared unobserved effects are assumed to be correlated with explanatory variables.

Random-effects models modify the Poisson parameter as:

$$\lambda_{ij} = \exp(\beta X_{ij}) \exp(\eta_j) \quad (5)$$

where λ_{ij} is the expected number of crashes for roadway entity i belonging to group j , and η_j is a random effect for observation group j . The most common model is derived by assuming η_j is randomly distributed across groups such that $\exp(\eta_j)$ is gamma-distributed with mean 1 and variance α . The Poisson model limits the mean and variance to be equal.

$$E[y_{ij}] = \text{VAR}[y_{ij}] \quad (6)$$

And the Poisson variance to mean ratio is $1 + \lambda_{ij}/\alpha$ with random effects.

Bivariate/multivariate models become necessary when modeling multiple crash types. For instance, the number of fatal crashes cannot increase or decrease without affecting the counts of property damage only (PDO) or injury crashes. This problem can be solved using bivariate/multivariate models since they obviously consider the correlation among the severity levels or crash types for each roadway entity or zone. Multivariate models have been employed such as multivariate Poisson model, multivariate NB model, and multivariate Poisson-lognormal model.

Recently, application of the Bayesian approach became popular for traffic crash studies. Bayesian methods provide a comprehensive and robust approach to model estimation. Moreover, Bayesian models do not depend on the assumption of asymptotic normality underlying classical estimation methods as maximum likelihood. Traditional estimation methods such as the least square estimation are designed to find single estimate point. However, Bayesian estimation focuses on the entire density of parameters. For instance, in classical statistics the prediction of out-of-sample data often involves calculating moments or probabilities from the assumed likelihood for y , $p(y|\theta_m)$, which is evaluated at the selected point estimate θ_m . However, the information about θ is contained in the posterior density $p(\theta|y)$ in the Bayesian method; thus, prediction is estimated based on averaging $p(y|\theta)$ over this posterior density. It was argued that among the benefits of the Bayesian approach are a more natural interpretation of parameter intervals, often termed Bayesian credible or confidence intervals, and the freedom of obtaining true parameter density. On the contrary, maximum likelihood estimates rely on normality approximations based on large sample asymptotic. New estimation methods assist in the application of Bayesian random-effects models due to pooling strength across sets of related units.

There are several unique characteristics of the macroscopic safety analysis, which must be considered in the methodology. The first one is the spatial dependence of traffic crashes. Most statistical models assume that the values of observations in each sample are

independent or randomly distributed. However, a positive spatial autocorrelation may violate this assumption, if the samples were collected from nearby zones. Many researchers found spatial autocorrelations in the traffic crash data. The second one is regarding the boundary problem. Since TAZs are often delineated by arterial roads, most crashes occur on zone boundaries. The existence of boundary crashes may invalidate the assumptions of modeling only based on the characteristics of a zone where the crash is spatially located. The third is the modifiable areal unit problem (MAUP), which is presented when artificial boundaries are imposed on continuous geographical surfaces and the aggregation of geographic data causes the variation in statistical results. These characteristics are discussed in the following sections.

Spatial Dependency

Spatial autocorrelation is a technical term for the fact that spatial data from nearby locations are more likely to be similar than data from distant locations. The existence of spatial autocorrelation in the crash data may invalidate the assumption of the random distribution. Thus, it is required to test for the presence of spatial autocorrelations in the data set before the model estimation. If the spatial autocorrelation is detected, the crash model should account for spatial effect. Many researchers showed that spatial autocorrelations are found in the traffic crash data, and commonly observed that accounting for the spatial autocorrelations significantly improves the crash model performance. Fig. 3 shows an example of the spatial dependency in crash data. As shown in the figure, crashes are concentrated in the west and southeast counties. On the other hand, northwest counties have much less crashes compared to other regions. It is a good example of the spatial dependency that the crash frequency from near counties is more likely to be similar than that from distant locations.

Figure 3 An example of spatial dependency in Florida.

Figure 4 An example of boundary crashes in Orlando, Florida.

Boundary Crash Problem

In the spatial analysis, boundary problems originate from ignoring the interdependences that occur from outside the boundary of zones. In the macroscopic analysis, the boundary problem is much more crucial and unique. Since TAZs are often delineated by arterial roads, most crashes occur on zone boundaries. **Fig. 4** displays an example of boundary crashes. The yellow lines in the figure are major arterials and red points show the location of crashes. As seen in the figure, the majority of crashes occur on or near the boundary of TAZs. The existence of boundary crashes may invalidate the assumptions of modeling only based on the characteristics of a zone where the crash is spatially located. One of the methods to solve the boundary crash problem is to estimate crash models separately for interior and for boundary crashes. Also, it is desirable to presume that boundary crashes are influenced by two or more adjacent zones (**Fig. 5**). Although the boundary crash issue in the macroscopic safety analysis is very important, not many research studies have addressed this issue. This is certainly an active area of further studies.

Modifiable Areal Unit Problem

The MAUP is present when artificial boundaries are imposed on continuous geographical surfaces and the aggregation of geographic data causes the variation in statistical results. Assuming that areal units in a particular study were specified differently, it is possible that very different patterns and relationships are shown. MAUP is composed of two effects: scale effects and zoning effect. Scale effects result from the different level of spatial aggregation. For example, traffic crash patterns are differently described in lower aggregation spatial units such as TAZs and higher aggregation units such as counties or states. Meanwhile, zoning effects are from the different zoning configurations at the same level of the spatial aggregation.

Figure 5 Separate modeling of interior and boundary crashes.

Still, few studies have addressed the MAUP on macroscopic traffic crash modeling to date. One of the important studies regarding the MAUP is conducted by [Abdel-Aty et al. \(2013\)](#). The authors conducted an interesting research regarding the effect from different zone systems. The authors compared crash models based on three different areal units BGs, CTs, and TAZs. The authors also discovered that the BG-based model had the larger number of significant variables for total and severe crashes compared to models based on other geographical units.

Macroscopic Contributing Factors to Traffic Crashes

Macroscopic crash studies that have been conducted typically have analyzed total crashes and sometimes explored crashes by severity level (i.e., total, PDO, injury, severe, fatal, etc.). Moreover, crash types/modes such as nonmotorized modes, for example, bicyclists or pedestrians, have been widely explored. In this section, contributing factors for the specific types or severity levels of the crashes are discussed based on results from previous studies carried out by [Hadayeghi et al. \(2003\)](#), [Noland and Quddus \(2004\)](#), [Kim et al. \(2006\)](#), [Naderan and Shahi \(2010\)](#), [Abdel-Aty et al. \(2013\)](#), [Lee et al. \(2014\)](#), [Lee et al. \(2015\)](#), [Chung et al. \(2018\)](#), and [Lee et al. \(2019\)](#).

Transportation Factors

Transportation data include traffic, roadway, and travel characteristics. **Table 1** summarizes the list of significant transportation factors to several key crash types (i.e., total, severe, bicycle, and pedestrian-involved crashes from the previously mentioned macroscopic safety studies). The identified factors were classified into positive or negative association categories. The positively associated factors are likely to increase crashes, while the negatively associated factors are likely to decrease the number of crashes.

“Vehicle-miles-traveled” and “total road miles” have frequently been used as a traffic exposure variable in the models. Other exposure (or surrogate exposure) variables such as bicycle-lane length and mode share of bicycles for bicycle crashes and pedestrian walking hours, and transit/pedestrian accessibility for pedestrian crashes were also found significant. Moreover, multiple studies showed that the percentage of length of high-speed roads increases total, severe, bicycle, and pedestrian-involved crashes. On the other hand, “volume-to-capacity” and “speed limit” have negative association with total and severe crashes (i.e., safer).

Work/college trip production is positively associated (i.e., more dangerous), but school/recreational trip production is negatively associated with total crashes (i.e., safer). Also, the number of intersections and intersection density are positively related to bicycle and pedestrian-involved crashes (i.e., more dangerous), respectively. It implies that both bicyclists and pedestrians are more vulnerable at intersections.

Table 1 Transportation factors in macroscopic safety studies

<i>Crash type</i>	<i>Positive association</i>	<i>Negative association</i>
Total	Vehicle-miles-traveled	
	Total road miles	
	Percentage or length of high-speed roads	Volume-to-capacity
	Speed limit	School/recreational trip production
	Work/college trip production	
Severe	Vehicle-miles-traveled	Volume-to-capacity
	Total road miles	Speed limit or average speed
	High-speed road length	Short commute time
Bicycle	Vehicle-miles-traveled	
	Bicycle-lane length	Low-speed road length
	High-speed road density	Average travel time to work
	Number of intersections	Mode share of cars
	Mode share of bicycles	
Pedestrian	Vehicle-miles-traveled	
	Pedestrian walking-hours	
	Intersection density	Provision of sidewalk
	Transit availability	People working at home
	Pedestrian accessibility	
	Percentage of high-speed road length	

Table 2 Demographic factors in macroscopic safety studies

<i>Crash type</i>	<i>Positive association</i>	<i>Negative association</i>
Total	Population Population density Minority population or percentage	Percentage of elderly people
Severe	Number of household Population density Minority population or percentage Percentage of working age people Percentage of children	Percentage of elderly people
Bicycle	Population Percentage of elderly people	Percentage of old-middle age group (45–64)
Pedestrian	Population Percentage of minority population Percentage of young-elderly Population (65–74)	Percentage of children (0–15) Percentage of elderly people

Demographic Factors in Macroscopic Safety Studies

Demographic data refer to data about the features of a population including but not limited to age, gender, and race/ethnic groups in the population. Multiple demographic factors were found significant for crashes (**Table 2**). “Population” and “population density” were positively associated with many crash types. For total, severe, and bicycle crashes, “percentage of elderly people” was negatively associated with crashes. However, it does not mean the elderly people are safer; but it might show that elderly people’s social activities are lower than young age group (15–25 years) and elderly people are less exposed to traffic crashes. It is noteworthy that the minority population (e.g., Hispanics and African Americans) is more vulnerable for total, severe, and pedestrian crashes.

Socioeconomic Factors

Socioeconomic data are defined as data of society and economy, which are related to employment, income, vehicle ownership, education level, crimes, and industry type. **Table 3** summarizes the socioeconomic factors to crashes in our study. “Total employment” was found significant and has positive effects on total and severe crashes. Also, “percentage of tertiary industry occupations” is negatively associated with pedestrian crashes. On the other hand, “percentage of the unemployed” increases the number of pedestrian crashes. It is interesting that “percentage of people working at home” is negatively associated with total crashes. This association is reasonable as people working at home do not need to commute and are thereby less exposed to traffic crashes.

“Income” is also a key factor in traffic safety. It was commonly shown that income is negatively associated with total, severe, bicycle, and pedestrian crashes. In other words, areas with higher income are likely to have a smaller number of crashes, while those with lower income tend to have a larger number of crashes.

Land-Use Factors

Land use is an important characteristic not only for traffic safety but also for transportation planning. Land-use characteristics determine the number of generated trip types by purpose, and also determine the modes of transportation. Previous macroscopic

Table 3 Socioeconomic factors in macroscopic safety studies

<i>Crash type</i>	<i>Positive association</i>	<i>Negative association</i>
Total	Total employment	Income Vehicle ownership Percentage of people working at home
Severe	Total employment	Income Education level
Bicycle	Alcohol consumption	Income Vehicle ownership
Pedestrian	Percentage of the unemployed Crime rates	Income Percentage of tertiary industry occupations

Table 4 Land-use factors in macroscopic safety studies

<i>Crash type</i>	<i>Positive association</i>	<i>Negative association</i>
Total	Mixed-use development areas Urbanization	—
Severe	Urbanization Commercial area	Residential area
Bicycle	Urbanization	—
Pedestrian	Commercial area Bars per roadway length	—

Table 5 Climate factors in macroscopic safety studies

<i>Crash type</i>	<i>Positive association</i>	<i>Negative association</i>
Total	—	—
Severe	Total precipitation Annual rain hours	Annual snow hours Annual fog hours
Bicycle	—	—
Pedestrian	Days with the maximum high temperature over 90°F	—

safety studies found several land-use factors (Table 4). For total crashes, “mixed-use development areas” and “urbanization” are positively associated with the number of crashes. Both “urbanization” and “commercial area” were positively associated with severe crashes. For bicycle crashes, “urbanization” was the only factor and it was positively associated. Pedestrian crashes have two land-use factors: “commercial area” and “bars per roadway length.” Lastly, “residential area” was negatively associated with severe crashes. In residential areas, the speed limit is relatively low and it is expected that crashes are less severe.

Climate Factors

Here, environmental factors include only one meaning: climate/weather factors. Several climate factors were found significant for crashes (Table 5). “Total precipitation” and “annual rain hours” are positively associated with severe crashes, while annual “snow hours” and “annual fog hours” are negatively associated. Lastly, it is interesting that an area with more “days with the maximum high temperature over 90°F” (i.e., very hot days) is positively associated with pedestrian crashes.

Recent Research Trends

Macroscopic safety analysis has attracted a great deal of attention in recent years as the promise of an effective tool that provides a broad-spectrum perspective to understand traffic crashes. However, the macroscopic safety analysis has shortcomings. First, although it is a useful tool to get an understanding of a broad spectrum of traffic safety influencers, specific problems (e.g., geometric design, signal, etc.) are often ignored. Second, it is not yet applied in the real world and not considered as a practical tool. Thus, the following research topics have been explored to improve the practicability of the macroscopic safety analysis: simultaneous analysis of microscopic and macroscopic safety, evaluating policies for safety, and integration with transportation planning. The studies discussed in this section are listed in the reference and further reading lists.

Simultaneous Analysis of Microscopic and Macroscopic Safety

There have been efforts to link or integrate microscopic and macroscopic safety. In one study, a comparative analysis was performed between macroscopic and microscopic level models using the same data. The study concluded that the microscopic model outperforms its counterpart (i.e., macroscopic model). Nevertheless, the macroscopic model needs less detailed data and provides suggestions not only for those directly related to traffic but also for those related to social, economic, political, and educational issues. Some researchers integrated macroscopic and microscopic analyses in the modeling stage. They commonly asserted that the modeling performance has improved when two scopes are combined since the information from each side could be shared with another (Fig. 6). Furthermore, the integrated model can be used to predict crashes at the microscopic (i.e., segment and intersection) and macroscopic levels (i.e., zone), simultaneously.

Figure 6 Information exchange between macroscopic and microscopic safety model components.

Evaluating Policies for Safety

Many policies are directly related to traffic safety but some are not directly related. For instance, motorcycle helmet law, bicycle helmet law, primary enforcement of seat-belt use, cell-phone use ban, etc., affect road users' decisions to use safety equipment and cell phones while driving. Moreover, some policies indirectly related to traffic safety include marijuana legalization, alcohol sale hours, etc. Macroscopic safety analysis is a great tool to evaluate such policies because policies and regulations are often based on political boundaries such as city, county, state, and nation.

There are two recent macroscopic safety studies that evaluated changes in policy. The first study explored the safety effects of the universal helmet law abolishment and reinstatement. The study adopted a before-and-after study with the comparison group and empirical Bayes at the county level. The study concluded that the outcomes of the helmet law changes are evident. The number of motorcycle fatal crashes increased by 26%–41% after the abolishment in Florida and decreased by 21%–26% after the reinstatement in Louisiana. The second study investigates the safety effects of the marijuana legalization. This study is state-based research as a state government determines whether marijuana is prohibited, allowed for medical purposes, or fully legalized for its jurisdiction. The results indicated that there are no significant changes after the medical marijuana legalization. However, 174.5% increase in the number of marijuana-involved fatal crashes was found after the decriminalization in Massachusetts, and 75.3% increase was observed in Connecticut after the medical legalization when decriminalization is already in place. Both Washington and Colorado experienced significant increases (31%–63%) after the full marijuana legalization.

Integration with Transportation Planning

As described earlier, there have been efforts to integrate traffic safety and transportation planning (i.e., transportation safety planning). A recent study proposed an idea to predict safety levels in the future using the estimated macroscopic safety models. This approach could become very useful to decide where we should provide countermeasures in advance to prevent serious crash problems in the future. **Fig. 7** compares the hot zones in 2010–12 and those predicted for 2040–42. Although the two figures have

Figure 7 Comparison of hot zones in 2010–12 and 2040–42.

Figure 8 Schematic illustration of the integration framework.

similar hot zones in some areas, it is clear that the hot zones in the future are not exactly the same as before. Thus, more efforts and resources should be assigned to the prospective hot zones, proactively.

Meanwhile, there have been other efforts to integrate traffic safety and planning. Two recent research studies proposed a combined modeling framework that could simultaneously predicts trips and safety simultaneously. With the suggested approach, more accurate and reliable estimation is achievable.

Fig. 8 shows the schematic illustration of the integration framework. The first component estimates the pedestrian total walking hours using climate, demographic, socioeconomic, and travel features. Subsequently, the predicted pedestrian total walking hours from the first component are provided to the second component (i.e., pedestrian fatality model) as an exposure. The integrated framework could provide better performance compared to the independent trip and safety models.

Summary and Conclusions

In recent years, macroscopic safety studies have been emphasized in accordance with requirements in the MAP-21 and FAST Acts. The macroscopic safety studies focus on zonal-based traffic crashes with demographic, socioeconomic, land use, and zonal level traffic/roadway characteristics. The macroscopic studies provide a broad-spectrum perspective, and also they suggest long-term policy-based countermeasures such as enactments of traffic laws/rules, police enforcement, education, safety campaigns, and area-wide engineering treatments. Numerous researchers have conducted macroscopic safety studies since the last decade and it is necessary to summarize their efforts at this point. Thus, this article summarized and reviewed geographic units, statistical methods, crash types, contributing factors, and current issues in macroscopic safety studies.

Researchers have chosen geographic units for their studies dependent on the objectives, perspectives, data availability, and so on. The geographic units can be census-based units (i.e., BGs, CTs, etc.), traffic-based units (i.e., TAZs, TADs, TSAZs, etc.), or political boundaries (i.e., counties, states, nations, etc.). Among the geographic units, TAZs have been most widely selected as geographic units because TAZs are the only traffic/transportation-related units. Also, since TAZs are also being used for transportation planning, it is easier to incorporate traffic safety into long-term transportation plans. Lately, TADs, which is aggregation of TAZs, are developed by the USCB. It is also related to transportation but limited research studies have been conducted based on TADs. It is necessary to investigate the possibility of TADs for macroscopic safety studies. Moreover, new safety spatial units (i.e., TSAZs) could be considered, which is exclusively developed for traffic safety analysis.

Poisson models and their variants have been developed and applied for traffic crash analysis. As in the microscopic safety studies, Poisson and NB models have been popularly used for the macroscopic safety research. Poisson model is the most basic and easy to estimate; however, it is unable to handle over-dispersion. NB model was suggested to overcome the over-dispersion issue in Poisson model. Moreover, some researchers applied Poisson-lognormal models, which was suggested as an alternative to the NB model for crash frequency data. It was claimed that Poisson-lognormal models are capable to provide more flexibility than NB models. Multivariate models are required when modeling multiple crash types simultaneously. Multivariate models consider the correlation among severity levels or crash types for each roadway entity of zone. Furthermore, application of Bayesian framework has been popular in the traffic safety field. Bayesian models do not depend on the assumption of asymptotic normality. Sampling-based methods of Bayesian estimation focus on estimating the entire density of parameters, whereas the traditional classical estimation methods that are intended for finding a single point estimate using the maximum likelihood approach. Furthermore, some studies started to apply the state-of-the-art techniques such as machine learning and deep learning. It is expected that applying such new techniques will provide much higher accuracies in crash prediction, especially, with Big Data. There are three important and unique characteristics of the macroscopic safety analysis, which must be considered in the analysis: (1) spatial dependency, (2) boundary crash problem, and (3) MAUP. Without considering these three features, it is likely that the results are biased and unreliable.

As summarized in this article, there are various contributing factors to crashes, including transportation, demographic, socioeconomic, land use, and climate factors. A good understanding of the effects of the factors is the first step to reduce crashes by providing effective countermeasures. There are several important research topics in the macroscopic safety analysis. First is the simultaneous analysis of microscopic and macroscopic safety. Each scope has its own advantages and it is not desirable to rely on only one scope. From the macroscopic analysis, we can understand a broad perspective of traffic crashes of areas. Then, detailed in depth analysis about the specific problem(s) at intersections or segments in the high risk zones. Furthermore, multiple recent studies began to apply macroscopic methodologies to assess policies. In this article, we took the universal helmet law and marijuana legalization as examples. Lastly, there have been efforts to combine traffic safety and planning. We are able to predict safety levels in the future by applying the macroscopic methodologies, and also planning and safety models could be integrated at the modeling stage.

The macroscopic safety analysis is still a relatively new tool in the traffic safety field. It has advantages including but not limited to providing a broad view of traffic safety situations, identifying not only traffic/roadway factors but also demographic, land use, and socioeconomic factors, being easily integrated with planning, and suggesting policy-based long-term countermeasures. Nevertheless, there are also challenges and disadvantages such as spatial dependency, boundary crash problem, MAUP, and limited practicability. In the future, we need to overcome these challenges and disadvantages of the macroscopic safety analysis, make it more practical, and save more lives from traffic crashes.

Introduction

Crash reportability discussed here will be limited to ground transportation and the data collection on and classification of crashes involving motor vehicles. This article will present the technical classification component of what constitutes a motor vehicle traffic crash from a traffic safety perspective for statistical reporting purposes. Events involving other transportation modes, although mentioned, will not be addressed in significant detail.

The technical terminology used in the article can be found in [ATSIP \(2017\)](#). This document has been in use in the United States for decades to support uniformity in reporting, classification, and analysis of motor vehicle traffic crash data. These data become the foundation for research and decision-making concerning traffic safety at the federal, state, and local levels in the United States as well as serving to inform the public and other users of the data.

While the *Manual on Classification of Motor Vehicle Traffic Crashes, Eighth Edition*, is an American National Standard and the primary source for the terminology in this article, the terminology and definitions therein are either a direct match or provide enough detail to be relatable to similar terminology used in other traffic safety applications outside the United States. For example, the intended application and relationship between the ANSI D16.1 terms “trafficway” and “roadway” are identifiable as almost directly parallel to the terms “road” and “carriageway” used in [UNECE \(2017\)](#). The United Nations Economic Commission for Europe (UNECE) document *Statistics of Road Traffic Accidents in Europe and North America* uses terminology presented in the jointly developed *Glossary for Transport Statistics*. The *Glossary for Transport Statistics* was developed cooperatively between the UNECE, the International Transport Forum (ITF), and Eurostat. All three documents are included as additional reference with this article and terminology is referenced between the documents in select areas of discussion.

Challenge of Defining Reportability

There are many different stakeholders involved that have an interest in the reporting of motor vehicle crashes. General examples include international organizations, national governments, private industry (e.g., automobile manufacturers, insurance companies), public health organizations, local governments, law enforcement, the court system, emergency services, and many others. Like the adage “beauty is in the eye of the beholder,” it is not a stretch to suggest that crash reportability is in the eye of the stakeholder. Each stakeholder has their own domain of interest or responsibility, and what is “reportable” to one, may not be to another.

There is also complexity created by circumstances that influence what crashes are reported in practice, to whom they are reported, and what happens with the data that results. Examples include the severity of the crash, its location, the type of vehicles involved, and the resource burden and availability of the resources to collect the data. In the case of crash severity, for example, a motor vehicle crash that produces a fatality or serious injury is almost certainly going to be reported. A fatal motor vehicle crash will involve action and data collection on the part of law enforcement, emergency services, healthcare services, insurance companies, possibly the court system, news media, and representation in local, national, and even international statistics. Furthermore, depending on other factors such as the location where the crash occurred (e.g., public versus private property) and the type of vehicles involved (e.g., large truck or railway train), other entities may be included or excluded in the chain of data collection and reporting. In contrast, a motor vehicle crash involving two passenger cars where only minor vehicle damage occurs, the parties involved may agree the damage is minor enough to go their separate ways with no reporting of the incident through any formal means.

The challenge that the disparity in reporting creates when comparing data from various sources is acknowledged in many traffic safety research publications. Often, statistical methods are employed to develop estimates to account for the disparity. This challenge in comparability of data at the international level is recognized in [UNECE \(2017\)](#) in the Introduction, in a section titled *Comparability of Data* it states, “The comparability of data is also subject to differences in road accident reporting standards. Notably, the number of accidents and the number of injuries may be underreported in some countries due to administrative or practical limitations,” ([UNECE, 2017](#), p. V). In other words, although UNECE can precisely define what they intend to represent in the document’s reports, influencers like the items mentioned above have a significant effect on what appears in the end data provided by the various sources.

Narrowing the Focus

A broad discussion of reportability of motor vehicle crashes addressing all the stakeholders and influencing factors is too complex to present in a single article. Additionally, before challenges in comparing end data and the effects that various domains of interest have on an individual stakeholder’s view of what is reportable to them can be understood, it is necessary to define what constitutes a motor vehicle crash. There are precise definitions that from a traffic safety perspective can be learned as a base standard for understanding reportability of motor vehicle crashes. Even limiting the scope to just defining motor vehicle crashes for classification, data collection, and statistical reporting, the topic is still complex. To develop a full understanding, it is necessary to present the terminology and its component parts along with examples of its application with real-world examples. Circumstances that fall outside the boundaries set forth in the definitions are not reportable as motor vehicle crashes. Defining those boundaries and providing examples will be the focus of the remainder of this article.

What is a Crash?

The term motor vehicle crash has component parts. To understand what is and what is not reportable as a motor vehicle crash it is necessary to scrutinize the terminology more closely. A crash within the context of the *American National Standard (ANSI D16.1-2017)*, *Manual on Classification of Motor Vehicle Traffic Crashes, Eighth Edition* is defined as “an unstabilized situation which includes at least one harmful event,” ([ATSIP, 2017](#), p. 22). There are two parts to examine and understand in this definition within the context of a motor vehicle crash. One is the concept of an unstabilized situation and its limitations and the second part is the concept of harmful events and the exclusions in this term that may affect reportability.

Unstabilized situations are “a set of events not under human control,” ([ATSIP, 2017](#), p. 20), in other words, they are unintended sets of events. A key exclusion from the term unstabilized situation is a set of events that result from deliberate acts. That is, any set of events that is deliberately caused (e.g., homicide, suicide, injury, or damage purposely inflicted, etc.) is not classified as a crash within ANSI D16.1. These acts are intentional and thus no unstabilized situation exists. Logically then, deliberate acts involving motor vehicles are not reportable for motor vehicle crash data collection purposes. A similar exclusion for suicides is identified in the Definitions and General Notes section of [UNECE \(2017\)](#). Specific examples of deliberate intent that are not considered to be a reportable motor vehicle crash include; a driver that commits suicide by driving their vehicle off a cliff, an enraged driver that purposely collides with another vehicle, or a terrorist that intentionally strikes pedestrians on a sidewalk.

ANSI D16.1 suggests that “Normally, the medical examiner or coroner will be the final authority on matters pertaining to cause of death whether or not an autopsy is performed,” ([ATSIP, 2017](#), p. 36). The word “normally” is used because identification of deliberate acts can be challenging in some circumstances pertaining to cause of death. This is particularly true in the case of a suicide. A suicide death is one where a person takes actions intended to result in their death. In the case of a suicide by motor vehicle, the injuries to a suicide victim are not likely to be medically different than those to a fatally injured driver in a reportable motor vehicle crash. Consequently, if there is a suspected suicide by motor vehicle, the determination of intent is typically made by law enforcement as part of their investigation. In resolution of suspected suicides by motor vehicle, without specific evidence showing intent, the events are usually captured as reportable motor vehicle crashes.

It is important to note that the exclusion of deliberate acts does not extend to intentional or imprudent driver behaviors that result in unintended events from being considered a motor vehicle crash. For example, a speeding motorcyclist that loses control in a curve, leaves the roadway, and strikes a tree would be involved in a motor vehicle crash. Likewise, an automobile driver under the influence of alcohol that fails to yield at an intersection and collides with another vehicle would be involved in a motor vehicle crash. This is true in both cases even though the speeding by the motorcyclist and over consumption of alcohol by the automobile driver were intentional and imprudent behaviors. The control loss by the motorcyclist and intersection collision involving the driver under the influence were not intentional and thus are unstabilized situations. In fact, addressing unsafe driving behaviors such as the examples above are the focus of many traffic safety initiatives.

The second part of the definition of a crash to examine is what constitutes a harmful event within the context of a motor vehicle crash. The harm can be broadly grouped as an event that produces either injury or damage. The term injury is defined as “bodily harm to a person,” ([ATSIP, 2017](#), p. 18). Excluded from being considered an injury are the immediate effects of diseases. For example, if a person that has coronary artery disease experiences a heart attack while driving, the heart attack itself is not considered as an injury in classifying any crash that may occur.

Damage is defined as “harm to property that reduces the monetary value of that property”, (ATSIP, 2017, p. 19). In rough parallel to the injury exclusion, excluded from being classified as damage is a mechanical failure of the vehicle. For example, if a vehicle being driven on an expressway experiences a tire blowout, the tire blowout itself is not considered as damage in classifying any crash that may occur.

The harmful events in a crash can be used to classify crashes for reporting purposes by the harm associated with the crash as a measure of severity. As it pertains to motor vehicle crashes, severity is commonly separated into a three-category set where the classifications are mutually exclusive. Understandably, crashes that produce harm to people are considered more severe than crashes that only harm property. Motor vehicle crash severity has a significant impact on whether it is formally reported, the entities to which it is reported, the data collected, and the downstream use of the data for safety research, applicability of laws and regulations, and resources committed.

A three-category classification that separates crashes by injury severity would be as follows (ATSIP, 2017):

1. Fatal injury crash: injury crash where at least one person dies as a result of injuries sustained in the crash within 30 days of the crash occurrence.
2. Nonfatal injury crash: injury crash other than fatal injury crash
3. Property damage only crash: crash other than an injury crash

Common in crash data collection is an expansion of the nonfatal injury component so that more detailed information can be captured about the nature of the injuries. For example, the Model Minimum Uniform Crash Criteria (MMUCC) is a guideline developed cooperatively between agencies in the US Department of Transportation (USDOT), the Governors Highway Safety Association (GHSA), and the US States. MMUCC provides a set of motor vehicle crash data elements that should be collected for traffic safety applications. This guideline since its beginning in 1998 has recommended a data element that separates injury severity into five categories (P5. Injury Status in MMUCC). In the Introduction, MMUCC supports this idea when stating, “Good data about motor vehicle crashes is critical to help explain yearly fluctuations in motor vehicle deaths and injuries and guide policy makers as they consider appropriate investments to reduce those deaths and injuries,” (NHTSA, 2017, p. 3). These same additional sub-classifications exist in ANSI D16.1 and can be used to further separate the injury component in order of severity as fatal injury, suspected serious injury, suspected minor injury, possible injury, and no apparent injury.

What is a Motor Vehicle?

ANSI D16.1 defines a motor vehicle as “any motorized (mechanically or electrically powered) road vehicle not operated on rails,” (ATSIP, 2017, p. 4). Within the manual, motor vehicles fall under a broad classification of transport vehicles. Transport vehicles are devices used for transportation including the device itself, connected transport devices (e.g., truck with a trailer), and any load of the transport vehicle. The broad classification of transport vehicle includes all modes of transportation. To separate in the classification those vehicles that operate on land from those that operate in the air or on the water, the term land vehicle is applied. Next, the term road vehicle excludes land vehicles that operate on railways. Road vehicles then can include transport vehicles such as automobiles, motorcycles, bicycles, trailers, horse-drawn carriages, etc. The final refinement comes in the term motor vehicle where motorization is required.

The Glossary for Transport Statistics goes through a parallel refining process using similar terms and definitions to define “road motor vehicles.” Within this document, the terms used include vehicle, road vehicle, and road motor vehicle. These term’s definitions include the same concept embedded within the ANSI D16.1 term transport vehicle, the concept of being used for transportation. *The Glossary for Transport Statistics* identifies that road motor vehicles are “normally used for carrying persons or goods or for drawing, on the road, vehicles used for the carriage of persons or goods,” (IWG, 2009, p. 43). The process of refinement of the terminology through successive definitions employed in both documents narrows and expands the scope for data collection and statistical reporting. For example, a crash involving an automobile, a bicycle, and a train would involve three vehicles, two road vehicles (train, bicycle), and one road motor vehicle (automobile).

There are few examples of note with respect to motor vehicles that pertain to reportability of motor vehicle crashes as applied in ANSI D16.1. First, like the prior example, crashes involving only a bicycle (without a motor) are not reportable as motor vehicle crashes. A second item of note in this area is that current classification within ANSI D16.1 includes a motorized bicycle as a class of motorcycle and thus as a motor vehicle. This distinction separates motorized bicycles from human-powered bicycles. In ANSI D16.1, human-powered devices propelled by pedaling are called pedal cycles. It should be noted that this same distinction does not exist in *The Glossary for Transport Statistics* where the term bicycle includes “cycles with supportive power unit” (IWG, 2009, p. 43).

Another class of device worth noting with respect to crash reportability within the context of ANSI D16.1 is a personal conveyance. These are devices “used by a pedestrian for personal mobility assistance or recreation,” (ATSIP, 2017, p. 4). Examples include skateboards, roller skates, wheelchairs, electric scooters, and others. A personal conveyance is excluded from being a transport device, thus these devices even when motorized are not classified as motor vehicles. Pertaining to reportability this means that if a person that falls and injures themselves while riding an electric scooter or skateboard, without the involvement of a motor vehicle, it is not reportable as a motor vehicle crash. Further, if a person on a personal conveyance is involved in a motor

vehicle crash (e.g., skateboarder struck in a crosswalk by an automobile), the motor vehicle crash would be classified as involving a single motor vehicle and the person operating the personal conveyance is a special class of pedestrian.

A last important motor vehicle crash classification point to make with respect to motor vehicles being transport vehicles is the concept that any load of the transport vehicle is part of that vehicle. Loads of vehicles include persons and property upon or set in motion by the vehicle, attached to and in position to move with the vehicle, or persons boarding or alighting from the vehicle (ATSIP, 2017, p. 2). This classification distinction means that if a person riding in the back of a pickup truck on a roadway falls from the truck bed and is hurt, they are classified as an occupant (passenger) of that vehicle. In this example, there has been an unstabilized situation and harmful event involving a motor vehicle resulting in a motor vehicle crash. The same would be true of cargo that falls from a vehicle while traveling on a highway. If injury or damage results from the falling or shifting cargo to the vehicle hauling the cargo or its occupants, other vehicles, persons, or property, or even damage to the cargo itself, then the vehicle has been involved in a motor vehicle crash.

What is a Motor Vehicle Crash?

Establishing that a crash is an unstabilized situation with a harmful event and that motor vehicles are mechanically or electrically powered road vehicles, the details of motor vehicle crashes is the next item to discuss. First, a motor vehicle crash is a class of transport crash. There are some key distinctions associated with transport crashes that can affect motor vehicle crash reportability. A transport crash requires that a transport vehicle in-transport is involved. To be involved means that an in-transport motor vehicle is directly associated with a harmful event. This can be injury to its occupants, other vehicle occupants, or other persons (e.g., pedestrian), or damage to the in-transport motor vehicle, other motor vehicles, or other property (e.g., a citizen's fence). When applied to motor vehicles, a motor vehicle is in-transport when it is in motion in any location, or on the roadway (travel lanes) of a trafficway in-motion or stopped (ATSIP, 2017, p. 15). The concept of being in-transport whenever on a roadway addresses that there are normal functions of transportation involving roadways where a vehicle is stopped. For example, stopped at a traffic control, when yielding before making a turn, or in traffic back-ups.

Excluded from being in-transport are motor vehicles that are parked. Parked motor vehicles are not in-motion and not on a roadway. In other words, the opposite of in-transport. In addition, because in-transport is associated with performing a transportation function, motor vehicles that are in use for performing construction, maintenance, or utility work associated with the trafficway are classified as a specific type of not in-transport motor vehicle using the term Working Motor Vehicle. That is, when engaged in these activities, these motor vehicles are performing a work function related to the trafficway, not a transportation function. What this means with respect to motor vehicle crash reportability is that if only a working motor vehicle is involved, there is no motor vehicle crash. For example, if two motor vehicles collide that are part of a mobile work activity such as repainting of the lane line markings, then there is not a reportable motor vehicle crash (no motor vehicle in-transport involved). It is important to note that the working motor vehicle exclusion is limited strictly to construction, maintenance, or utility work associated with the trafficway and only applies during the period that the work is being performed. For example, a highway maintenance vehicle, that is, traveling from one work site to another would be classified as in-transport. Also, of note, the term working motor vehicle does not extend to other vehicles that are associated with a business function (e.g., delivery vehicles, trash trucks) or being driven by people as part of their jobs (e.g., law enforcement on patrol, taxi drivers). These vehicles are not classified as working motor vehicles. A classification of in-transport or not in-transport is about identification of vehicles serving a transportation function for crash data collection and statistical reporting purposes.

Another key distinction is that transport crashes, as events associated with transportation, exclude incidents that directly result from a cataclysm. A cataclysm, as defined in ANSI D16.1, includes an avalanche, landslide/mudslide, hurricane, cyclone, downburst, flood, torrential rain, cloudburst, lightning, tornado, tidal wave, earthquake, volcanic eruption, damage from very large hail, and any wind above the minimum speed associated with a category one hurricane (ATSIP, 2017, p. 21). The exclusion notes that the timing must be such that the cataclysm is occurring at the time of the crash. For example, if rising floodwaters sweep a vehicle from the road, the incident would not be a transport crash, but rather the result of a cataclysm. However, if after the flood waters had receded, a vehicle lost control due to a portion of the roadway being damaged during the prior flood, there would be a transport crash and a reportable motor vehicle crash.

Lastly, although other land vehicles can be involved, if any aircraft are involved it is classified as an aircraft accident. The same would be true, if any watercraft were involved; absent any aircraft involvement as aircraft accidents are given higher classification priority. For example, if an airplane or helicopter crashes into motor vehicles on a freeway, the incident is classified as an aircraft accident even though it involved motor vehicles in-transport.

Additionally, because the most likely interaction is between motor vehicles and railway trains, both land vehicles, there is special consideration given to these incidents. If there is any harmful event involving the railway train prior to the involvement of the motor vehicle in-transport, then the incident is classified as a railway accident and not a reportable motor vehicle crash. For example, if a cargo train experiences a derailment and cargo from the overturned rail cars falls on motor vehicles traveling on the adjacent highway, there is no motor vehicle crash. It is a railway accident because of the initial harmful event involving only the railway train. However, if a railway train and an in-transport motor vehicle collide at a railway crossing, there would be a reportable motor vehicle crash.

What is a Motor Vehicle Traffic Crash?

The significant impact crash severity has on whether a crash is formally reported, the entities to which it is reported, the data collected, and the downstream use of the data is mentioned in the earlier discussion of harmful events in crashes. Another very significant factor in these same areas is the classification of the motor vehicle crash based on the location where it occurs. The key term associated with location classification is with respect to involvement of a trafficway. This important component is used to separate motor vehicle crashes into two classes, motor vehicle traffic crashes and motor vehicle nontraffic crashes. The interest in this separation is identification of motor vehicle being used for transportation within the transportation infrastructure from those that are not. For example, if a citizen backing in their private driveway impacts a pedestrian in the driveway, it would be classified as a motor vehicle nontraffic crash. While there is interest in these crashes for safety research (e.g., effectiveness of back-up cameras or pedestrian detection systems), this example does not involve the shared transportation infrastructure. Additionally, given that ANSI D16.1 is a Manual on Classification of Motor Vehicle Traffic Crashes and that motor vehicle traffic crashes are predominantly what is used in research, the discussion of motor vehicle crash reportability would be incomplete without addressing this concept.

As defined in ANSI D16.1, “A traffic crash is a road vehicle crash in which (1) the unstabilized situation originates on a trafficway or (2) a harmful event occurs on a trafficway,” (ATSIP, 2017, p. 24). In classification, motor vehicle crashes and traffic crashes are both transport crashes but note that traffic crashes do not require a motor vehicle be involved. For example, if a bicyclist riding on a roadway falls and is injured after being struck by the opened door of a motor vehicle parked in a parking lane, the crash would be classified as a traffic crash. It is not a motor vehicle crash because there was no motor vehicle in-transport involved. The bicycle is a road vehicle, but not a motor vehicle. The parked motor vehicle is not in-transport. So, although both transport crashes, traffic crashes are separate from motor vehicle crashes based on the involvement of a motor vehicle in-transport. Many countries and some US states collect and report data on traffic crashes including those that do not involve a motor vehicle. For example, Sweden includes in its official statistics single bicycle crashes, if they happen on public roads allowing motor vehicles. Understanding this classification terminology is imperative to compare data between various reporting entities.

Narrowing the classification, motor vehicle crashes differ from motor vehicle traffic crashes in that the latter involve a trafficway. As defined in ANSI D16.1, “A trafficway is any land way open to the public as a matter of right or custom for moving persons or property from one place to another,” (ATSIP, 2017, p. 3). The *Glossary for Transport Statistics* has a similar definition in its term “Road” which is defined as “Line of communication (traveled way) open to public traffic, primarily for the use of road motor vehicles, using a stabilized base other than rails or air strips,” (IWG, 2009, p. 39). Note that neither definition makes mention of ownership of the trafficway. That is, there is no distinction made between public ownership versus private ownership in these terms. Just that it is a land way open to the public for transportation. Consequently, in addition to government or publicly owned and maintained trafficways, privately owned land ways open to the public for transportation are trafficways.

The most common example would be a parking lot way. Parking lot ways most frequently occur in shopping, business, or apartment home complexes where the land ways within these locations are privately owned but fully accessible to the public for transportation to the stores, businesses, or apartment homes. A parking lot way is defined in ANSI D16.1 as a “Land way which is used primarily for vehicular circulation within parking lots and for vehicular access to parking lot aisles. Parking lot ways in parking lots open to the public are trafficways,” (ATSIP, 2017, p. 29). The impact of this is that motor vehicle crashes that occur on a parking lot way are motor vehicle traffic crashes. This is true even given that most parking lot ways are owned and maintained by whatever private entity owns the land on which the parking lot way is built.

An important use for motor vehicle traffic crash data is to plan and evaluate investment by governments in the transportation infrastructure. To address this need, motor vehicle traffic crashes are typically identified in data collection as occurring on public or private property so that the ownership and maintenance responsibility of the trafficway can be identified. The interest here is to be able to separate from the body of motor vehicle traffic crashes those that involve government or publicly owned and maintained transportation infrastructure and thus require public funds.

As an example, the National Highway Traffic Safety Administration (NHTSA), the agency within the US Department of Transportation (USDOT) that is tasked with reducing deaths, injuries, and economic losses from motor vehicle crashes, separates its data collection so the distinction can be made between motor vehicle nontraffic and motor vehicle traffic crashes. Further, within the motor vehicle traffic crash data, there is data available to separate publicly from privately owned trafficways to address the interest in publicly funded transportation infrastructure. Specifically, NHTSA’s Fatality Analysis Reporting System (FARS) that has been in existence since the 1975 is a nationwide annual census of motor vehicle traffic crashes within the 50 States, the District of Columbia, and Puerto Rico. Provided within the FARS dataset of fatal motor vehicle traffic crashes is an element called Ownership. The 2019 FARS/CRSS Coding and Validation Manual identifies that “this element identifies the entity that has legal ownership of the segment of the trafficway on which the crash occurred” (NHTSA, 2019, p. 81), thus this data element provides the granularity to separate motor vehicle traffic crashes that occur on publicly owned trafficways from those that occur on privately owned property. Additionally, because NHTSA’s responsibility is not just motor vehicle traffic crashes, it maintains another database known as the Not-in-Traffic Surveillance System (NiTS). NiTS purpose is to collect and provide counts and details on fatalities and injuries that occur in nontraffic crashes and in noncrash incidents.

Biography

John McDonough is the President of the National Institute for Safety Research. He has been the principal instructor for the National Highway Traffic Safety Administration's (NHTSA) Fatality Analysis Reporting System (FARS) and Crash Report Sampling System (CRSS) since 2007. In addition to his work with NHTSA, Mr. McDonough has served as a subject matter expert and trainer for the Federal Motor Carrier Safety Administration's (FMCSA) Data Quality Improvement Program training law enforcement in large truck and bus crash data collection. He has also assisted numerous states in crash report redesign, training law enforcement in crash classification, and by writing crash report instruction manual and training class content. Mr. McDonough has significant experience with traffic safety data standardization to include being a member of the ANSI D16.1 Manual on the Classification of Motor Vehicle Traffic Crashes 7th and 8th Edition Workgroup (2007) and Consensus Body (2017), serving on the Model Minimum Uniform Crash Criteria (MMUCC) Expert Panel (2008, 2012, 2017), and as a team member of the USDOT Data Standardization/NHTSA Data Compatibility Workgroup (2005–10).

Introduction

This article focuses on traffic safety in the roadway system but similar discussions could be targeted toward rail, airline, shipping, and other transportation sectors. In addition, personal safety in the transportation system as well as security issues relating to extreme weather events, natural disasters or terrorism could be covered by similar analogies and comparisons.

Safety can be described and measured in many ways. We often hear expressions used by the public as well as by politicians such as, “Safety is paramount,” or “It has to be completely safe.” Sometimes people do not want to see a change from what they are used to, because they feel any alternations from their daily routine may jeopardize their safety and make it less safe. For that reason, it is often assumed that our current system is “safe,” However, our current roadway system is far from safe and will remain unsafe as long as we see no or very few serious injuries and fatalities. That is definitely true if we look at safety from society’s perspective, or compare it with regards to dangers we are exposed to in most other daily activities.

One way of improving traffic safety in our roadway system is to make sure that all its components—roadways, vehicles and operators—with respect to design and operations, meet all standards and guidelines. This is often referred to as Nominal Safety. If meeting such standards and guidelines guarantee absolute safety, then having high Nominal Safety would guarantee high if not full safety. Before dwelling further into Nominal Safety, let us look at a few alternate definitions of safety.

Types of Safety

Safety and security of a transportation system can be measured and evaluated in many ways. The main ways are often classified as:

- Subjective or perceived safety
- Objective or substantive or actual safety, that is, “count” of crashes by severity
- Theoretical safety
- Nominal safety = conformance to warrants/guidelines/standards

First, let us look briefly at subjective safety. This is elaborated in the article “Risk Perception and Risk Behavior in the Context of Transportation.” But let us discuss it here as well.

Typically, subjective safety refers to an ordinary road-user’s perception of safety when being involved in an activity, such as driving a car, walking or traveling by an airplane. Subjective safety can, however, also refer to an “expert’s” opinion—that is, the opinion of a traffic engineer, police officer, motor journalist, or other professional—regarding the safety of, for example, a location or a roadway condition. When an engineer makes the assessment, it is sometimes called engineering judgment. This can be done as an estimate of its expected number of accidents but typically is done in some other way. One such other way is to evaluate whether the entity meets guidelines and standards or not. Other measures of subjective safety, as assessed by experts, may be frequency of road-user violations or number of near misses or traffic conflicts. These surrogate measures may have a direct relationship to objective safety. However, subjective safety is from here on in this article defined as the perception of ordinary road-users. This safety is by itself of interest. If a location is perceived of as unsafe, drivers may avoid it and that may cause them to use routes that are less desirable from a community’s perspective; or it may cause them to use a different mode of transportation or canceling their trip altogether. And, even if they do not change mode or avoid the location, it may cause stress and fear. For example, people who dread a dangerous location (a bridge, a high-speed traffic circle, or a narrow road), may believe there are no alternatives, so they cannot avoid the location. Will this affect the drivers’ health? Will it affect their demeanor? Will it affect the way they will interact with other people later that day? Their level of anger? Their driving once they have exited that location? The answer to all those questions may be: Yes to

some extent but probably not drastically. However, anything can, of course, be that last straw which breaks the camel's back. On the other hand, drivers who perceive a location to be unsafe are typically more careful at that site. This may lead to fewer crashes than if people view the location as safe. Some safety advocates therefore argue that engineers should try to design locations so that they are safe but look or feel unsafe. A final question: Is there a connection between perceived safety and whether a location meets nominal safety standards or not? We will not try to answer that question here. However, if most locations meet nominal safety standards, people may expect that to be the case everywhere.

Objective or substantive or actual safety refers to the final result on safety as measured through a "count" of crashes or accidents. This count is not the random outcome that a location has experienced, or will experience, but the long-term expected number of crashes if traffic volumes and all other parameters could be held constant. It would make little sense to state that the safety of a location has deteriorated by 50% from 2017 to 2018 because the number of crashes went from two to three. Also, it is not only just the number of crashes that affects whether a location has high or low actual safety, but also it is the severity of those crashes. Furthermore, exposure also matters. It makes little sense to say that riding a motorcycle has higher objective safety than riding in a car just because fewer people are injured or killed on motorcycles than in cars. For example, the US National Highway Traffic Safety Administration ([NHTSA](#)) reports that 5172 motorcyclists were killed in 2017 in the United States whereas 23,708 passenger-vehicle occupants were killed. Motorcycle crashes account for about 14% of all traffic fatalities in the United States, but motorcycle traffic represents only 0.6% of vehicle miles traveled on America's roads. So, the risk per mile is much higher for motorcyclists than for automobile occupants ([FHWA, 2019](#)). On the other hand, passenger car travel can be seen as the greater threat to public health since more people die that way.

With theoretical effect on safety we typically mean the effect a countermeasure ought to have if people behaved in a "theoretical" way. For example, if we have a factory located just off a major road and there are 50 vehicles turning off to that factory every day causing, on average, one crash per year, we could expect ten crashes per year if the number of vehicles turning off was increased tenfold to 500 a day, as long as we did not change the geometric layout or anything else. Will that be the expected result? Not necessarily. Higher turning volumes may lead to an increased awareness among drivers who go through that location on a daily basis. That, in turn, may lead to less of an increase in the number of crashes than we "theoretically" calculated. Several studies have shown that risk compensation is real (even if risk homeostasis is not), that is, subjective risk perception influences a person's behavior and, therefore, the actual safety effect cannot easily be calculated with simple mathematical formulas.

The final "type" of safety, nominal safety, is the focus of this article and will be covered next.

Nominal Safety—Conformance to Guidelines

Nominal safety is evaluated by looking at compliance with standards, warrants, guidelines, and sanctioned design procedures. Standards and guidelines vary from country to country and even within countries. So, what is nominally safe in one country may not be safe in another one. Also, state standards may not be the same as municipal standards, and municipal standards may not apply to private roads. Let us first look at some of the more known guidelines for roadways.

For road traffic in the United States, the American Association of State Highway and Transportation Officials (AASHTO) Green Book, *A policy on geometric design of highways and streets*, give geometric standards that are to be followed for major roads, the so-called National Highway System (NHS) ([AASHTO 2018](#)). These standards can also be followed on lower-priority roads but the road administrator can set their own geometric standards for those roads. Title 23 of U.S. Code §109 states, "projects (other than highway projects on the NHS) shall be designed, constructed, operated, and maintained in accordance with State laws, regulations, directives, safety standards, design standards, and construction standards." The AASHTO Green Book is updated every few years and the latest edition, the seventh, was published in September 2018 and adopted by the Federal Highway Administration (FHWA) on November 1, 2018, as stated in Federal Register/Vol. 83, No. 212/Rules and Regulations 23 CFR Part 625: "This final rule updates the regulations governing design standards and standard specifications that apply to new construction, reconstruction, resurfacing (except for maintenance resurfacing), restoration, and rehabilitation projects on the National Highway System (NHS). In issuing this final rule, FHWA incorporates by reference the latest versions of design standards and standard specifications previously adopted and incorporated by reference, and removes the corresponding outdated or superseded versions of these standards and specifications. Use of the updated standards is required for all NHS projects authorized to proceed with design activities on or after the effective date of the final rule. This final rule is effective December 3, 2018." In summary, the State highway departments, working through AASHTO develop design standards through a series of committees and task forces. FHWA contributes to the development of the design standards through membership on these working units, sponsoring and participating in research efforts, and many other initiatives. Previous AASHTO Green Books were published in 1984, 1990, 1994, 2001, 2004, and 2011. Prior to the Green Book, AASHTO or its predecessor, AASHO, published, for example, a Policy on Geometric Design of Rural Highways in 1954 and 1965; and a Policy on Design of Urban Highways and Arterial Streets in 1973. AASHTO also publishes standards and specifications for construction materials, for bridges, and other roadway transportation areas.

Other countries have similar national guidelines for geometric design. For example, Sweden has *Vägars och gators utformning* (VGU) (design of roads and streets), which is published jointly by [Trafikverket](#) (the Swedish Transport Administration) and an organization with members from the Swedish municipalities and counties. The current edition is from 2015 and replaced the 2012

edition. The design recommendations sometimes coincide with those in the AASHTO Green Book but often do not. The Swedish guidelines are considered rules and need to be followed on State roads, which currently, in 2020, make up around 98,500 km. For municipal roads, currently around 42,300 km, and private roads getting State support, around 74,000 km, VGU standards are voluntary and seen as advisory only.

In the United Kingdom (UK), there is the Design Manual for Roads and Bridges (DMRB), which is a series of 15 volumes that provide standards for the design, assessment and operation of trunk roads in the UK, and, with some amendments, the Republic of Ireland. It also forms the basis of the road design standards used in many other countries. Volume 6 gives Road Geometry and other volumes cover Highway Structures, Geotechnics and Drainage, Pavement Design and Maintenance, Traffic Signs and Lighting, Traffic Control and Communications, Environmental Design and Economic Assessment.

All guidelines for road design and operation in Germany are published by the Forschungs gesellschaft für Straßen- und Verkehrswesen (FGSV) (Road and Transportation Research Association), a non-profit organization similar to the Transportation Research Board (TRB) in the US. Guidelines are developed by technical committees, with members from state and federal governmental organizations, private industry, consultants, and universities. Guidelines are subject to continuous change and development. The first guidelines were issued after the first World Road Congress in 1908, with an emphasis put mainly on the geometry of single vehicles (motor vehicles, long horse carts). Then requirements for moving motor vehicles, with respect to driving dynamics, were added in the 1920s and 1930s. Nowadays, vehicles interacting with each other are the focus of design considerations. At all times, traffic safety has been the focus but in later years, environmental issues, and ecological sustainability, are also priorities. In the last decades, new principles for road design guidelines are being implemented. Although driving kinematics still have to be observed, principles like readability or self-explaining properties of the road are receiving higher importance. This includes trying to better understand how human factors and psycho-physiological properties of drivers should be considered in design in a systematic way (Lippold et al., 2015).

With respect to highway signs and markings, the United States has the Manual on Uniform Traffic Control Devices for Streets and Highways (MUTCD). The MUTCD has been administered by the FHWA since 1971, and is a compilation of national standards for all traffic control devices, including road markings, highway signs, and traffic signals. It is updated periodically to accommodate the nation's changing transportation needs and address new safety technologies, traffic control tools, and traffic management techniques. On December 16, 2009 a final rule adopting the 2009 Edition of the MUTCD was published in the Federal Register with an effective date of January 15, 2010. It was stated that states must adopt the 2009 National MUTCD as their legal State standard for traffic control devices within two years from the effective date. Therefore, by January 15, 2012, States were required to have adopted the National Manual or have a State MUTCD/supplement that is in substantial conformance with the National Manual. The 52 FHWA Division Offices (50 States plus Puerto Rico and Washington D.C.) reviews any State MUTCD or supplement to determine if it is in substantial conformance with the National MUTCD. As of January 2020, about 16 states have adopted the national manual, 24 have adopted the national manual along with State supplements and 10 have adopted their own State MUTCD (FHWA, 2020). The content of State MUTCDs is similar to the national one. For example, all States use double yellow centerlines to indicate that passing is a bad idea, but in some states, the striping means that it is illegal to cross the centerline to pass any vehicle while in other states it is legal to pass slow-moving vehicles and in some states, it is an advisory rule only. In some other countries, double centerline markings mean that it is illegal to cross the centerline for any purpose, such as to turn left into a driveway. So, the exact meaning of a markings varies from jurisdiction to jurisdiction and meeting nominal safety—having “correct” striping—may therefore have different implications on objective safety.

It should also be pointed out that the AASHTO Green Book typically uses “should” and sometimes “may”. The word “shall” or “must” are seldom used, so there is some flexibility in the policy. On the other hand, the current MUTCD uses the word “should” 2627 times, “shall” 3046 times, “may” 1788 times, and “must” 95 times.

Other countries have similar manuals as the MUTCD but few if any roadway signs are universal. The stop sign is the only real exception. However, most countries outside North America have signs conforming to the Vienna Convention. All European countries, except Ireland, and most countries in Asia and some in Africa and South America have adopted the Vienna Convention on Road Traffic, which is an international treaty designed to facilitate international road traffic and to increase road safety by establishing standard traffic rules among the contracting parties. The convention was agreed upon at the United Nations Economic and Social Council's Conference on Road Traffic in 1968 and came into force in May 1977. It is currently ratified by 78 countries. The convention part that contains rules on road signs and signals was amended in 1993 and 2006.

So, if different countries have different standards, why is that? Are nominal safety standards not based on thorough analysis of what is safe? Sometimes that is not the case. Hauer (1997) writes: “The field of road safety abounds with strongly held but unfounded opinions. Thus, most road users believe that traffic signals enhance safety; they go to their gut feeling. Most traffic engineers believe that four-way stops enhance safety only where warranted by the Manual of Uniform Traffic Control Devices; they go by professional folklore. In road safety, gut feeling and folklore are frequently wrong.” The latter was evaluated in a study of the effect of all-way stop as a function of percent minor volume. They found that there was very little if any correlation between meeting the guideline and objective safety (Simpson and Hummer, 2010).

Consequences of Nominal Safety Deviating from Objective Safety

When analyzing the safety of an intersection, segment of roadway, or other transportation facility, an engineer might encounter that the entity meets or does not meet one or both of the two safety types nominal safety and objective safety. Whether it meets subjective safety will not be discussed here.

Whether an entity meets nominal safety or not, can typically be evaluated in a fairly straightforward way by looking at whether standards are met or not. For example, are sight distances sufficiently long, is grade below allowed maximum value, and are radii above the minimum required? Even if the guidelines say “should” rather than “shall” it is clear that nominal safety has not been met unless the standard is met.

Whether an entity meets objective or substantive safety is somewhat harder to evaluate since we in road traffic do not have clear guidelines to what acceptable risk should be. That is discussed in a separate article written by Claes Tingvall [to be cross-referenced to article 10099: Acceptable risk by Claes Tingvall]. If we follow Vision Zero ideas, the focus of safety should be on avoiding fatalities and serious injuries. However, what is then acceptable? For the European Union (EU) rail system, it is stated that “for technical systems where a functional failure has credible direct potential for a catastrophic consequence, the associated risk does not have to be reduced further if the rate of that failure is less than or equal to 10^{-9} per operating hour (EU Commission, 2009). If we interpret this to convey that we should accept no more than one fatality per 10^9 h of travel, how many fatalities per year would we then accept in rail traffic in the EU? Rather than answer that, let us convert acceptable risk to fatalities per distance, especially since people seldom want to travel a certain time but rather a certain distance, to get to their destination. It is difficult to find estimates of average train velocities, and it can be argued that stopped time should or should not be included. Let us here assume that trains move at an average speed of 80 km/h (50 mph). That means that we would accept up to one fatality per 80 billion kilometers of travel or 0.0125 fatalities per billion kilometers traveled. In 2018, rail passenger transport in the EU was estimated at 472 billion passenger-kilometers (Eurostat, 2019). That means that we would accept up to six fatalities per year among train passengers in order to state that they are objectively safe. This may be a considerably tougher standard than intended since a failure resulting in catastrophic consequences certainly could kill more than one person per incident.

In EU-28, a total of 219 rail passengers were killed in the 5-year period 2012–16 (European Union Agency for Railway 2018), giving an average death toll of 44 per year. That includes passengers killed in collisions and derailments as well as falling on board or when alighting or boarding trains, etc. excluding only confirmed suicides. For example, in 2015, only eight people were killed in collisions as passengers of trains and none were killed in a derailment, whereas a total of 27 passengers died that year according to the numbers cited above. Still, if we did set a goal of having no more than six people per year being killed, it was not met for most years. Overall, with 44 fatalities per year, EU-28 saw around 0.09 fatalities per billion passenger km. (Besides numerous victims at grade crossings as accidents and suicides, which we will not discuss here.)

If we look at commercial airlines in the United States, to get another estimate of actual fatality risk, and include all crashes (and other accidents) since January 2002, we have had 130 people get killed on US airlines (with no one killed between February 2009 and the writing of this article in early 2020) and another three people killed traveling by a foreign airline (Asiana Airlines, crash in 2013) in the US, for a total of 133 fatalities in the US. So, from 2002 to the beginning of 2020, 18 years, we saw on average 7.4 fatalities per year. And, if using 2018 U.S. passengers travel mileage, 730.7 billion passenger-miles by plane, which is 1176 billion passenger-km, as exposure, we get an estimate of passenger flight distance. Travel volumes have increased over this time and the average travel mileage may be around 1000 billion km/year. That means we saw around 0.007 fatalities per billion km which is clearly below the desired 0.0125 fatalities per passenger-km as discussed for trains above. And, if we look at the latest 10 years only, with three fatalities in total, we would be at around 0.0003 fatalities per billion person km, which is a tiny fraction of the desired 0.0125. So, we could deem US air travel to be objectively safe.

On the other hand, if we look at automobile travel, did motor vehicles keep its occupants “safe,” meaning below 0.0125 fatalities per billion km? No, let’s look at the US, using 2017 data. The US had an official VMT of 3,212,670 million miles in 2017 according to FHWA. With an average of 1.3 occupants per vehicle, that translates to 4,176,470 million people (or passenger) miles or 6,719,940 million people-km. And, if we accept 0.0125 fatalities per billion km of travel, we would accept 84 automobile-related fatalities in the US in 2017. In reality, the US saw over 37,000 fatalities in 2017 and 23,551 of those were occupants of the motor vehicles according to NHTSA. That is 280 times what we could have as an objective required safety level, a safety level which is met by commercial airlines in the US and almost met by trains in Europe. European roads do quite a bit better than US roads, but are still far riskier than the desired level as outlined here. The EU has seen right around 12,000 occupant fatalities per year in later years (2013–16). Finally, it should be noted that there are people who travel by car in Europe as well as in the US who think US airliners seem too dangerous and do not want to fly, but we do not discuss subjective safety here.

An alternative definition of objective safety, when looking at a specific location is to say that it is safe if there has not been a single crash there in the last three or five years. However, that may sometimes be too strict, unless we have a true Vision Zero approach; and sometimes too liberal, since a location with very low traffic volumes may be objectively unsafe even if there has not been a single reported crash for many years. Note that having no crash in 3 years is not surprising if the expected number of crashes per year is very low, for example, 0.1. But imagine that this is an intersection between two driveways that serve one-family homes and it is traveled by only a few people per day. One crash every 10 years would obviously not be considered safe.

Another completely different way to define minimum required objective safety is to say that risk, as measured in crashes per some type of exposure, should not be higher than a certain number of standard deviations above the state average for such a facility. This reasoning builds on the belief that people would not venture out into traffic if safety, on average, was not acceptable, and since people do travel by car (and other modes that have even higher risks), they “obviously” think that today’s average risks are okay, but they may not find a specific location safe if it is significantly more dangerous than an average one. This reasoning makes little sense. Why would Americans be objectively safe driving through an intersection that is more likely to kill them than one in, say, the UK, that engineers in the UK find to be objectively unsafe since it is significantly more dangerous than the average intersection in the UK? Still, this is how high-crash locations are selected in many if not most countries.

If we use the evaluation of objective safety which is typically used around the world, for high-crash locations, as described in the previous paragraph, we can distinguish between four possibilities:

- Case A: nominal safety—meeting standards, objective safety—meeting standards
- Case B: nominal safety—not meeting standards, objective safety—meeting standards
- Case C: nominal safety—meeting standards, objective safety—not meeting standards
- Case D: nominal safety—not meeting standards, objective safety—not meeting standards

Case A is obviously what we desire.

In Case B, the roadway geometrics do not conform or meet the standard-based analysis. But if it still is objectively safe, it will not be a safety concern for society. However, it may be a liability concern for engineers and others when crashes do occur, even if there are very few crashes per million entering vehicles. Either the location needs to be reconstructed so that it meets the standards, or the standards should be changed. The latter is the case if we can identify many locations with similar non-conforming design that on average function with a high degree of safety.

In Case C, the roadway meets all standards and one could by mistake consider this to be a safe roadway. However, road users obviously misinterpret something or behave in unintended ways, and redesign—or enforcement or education—is needed more or less immediately.

In Case D, the roadway geometrics do not conform or meet a standards-based analysis and objective safety analysis shows that there are many crashes. It is obvious that these locations should be reconstructed, or changed in some other way, immediately. However, money is not always available and temporary measures may have to be taken, such as drastic reduction of the speed limit combined with police enforcement of the speed until reconstruction can occur.

We could add two more cases to this analysis. That is when objective safety is unknown because the location was just built or reconstructed and similar sites cannot easily be used for estimating objective safety. If that is the case, an evaluation of nominal safety may be all we can do. If nominal safety is met, we may be able to let the location be unevaluated with respect to objective safety until we have data. If nominal safety is not met, we may need to do conflict studies or evaluate objective safety in some other way to assess what is immediately required.

Discussion

Nominal safety means that standards are followed. This typically means that drivers know what to expect with respect to horizontal curve radii, sight distances, roadway widths, striping, signage, etc. Understanding rules and being able to predict what geometric characteristics will follow a hill crest or horizontal curve should help safety. Being surprised or not understanding what is expected of a driver ought to lead to lower safety. But why then does the US, which has stricter and probably better developed standards than any other country, have higher fatality rates—lower objective safety—than almost all other industrialized countries if safety is measured as fatalities per capita? And, even if measuring fatality rates as fatalities per million kilometers traveled (or driven), the US has higher rates than many other countries. For example, in 2019, Sweden had 2.62 fatalities per million vehicle km (0.42 fatalities per hundred million vehicle miles (HMVM)) whereas the US had a fatality rate that was between two and three times that. Obviously, having high nominal standards, and typically meeting them, does not guarantee objective safety.

Acknowledgment

I would like to acknowledge Dr. Eric H. Shimizu, PE, PTOE, Principal Engineer and Regional Director for Smart Cities and Connected Vehicles at DKS Associates, Seattle, Washington, for developing a first outline of an article on Nominal Safety.

Biography

Per Erik Garder is a professor of civil engineering at the University of Maine, USA, since 1992. He has a PhD from Lund University in Sweden and he was a faculty member of the Royal Institute of Technology (KTH) in Stockholm, Sweden (1983–92). His research interest is focused on forecasting, designing and evaluating facilities with emphasis on traffic safety.

Background

The demand for passenger and freight transportation has substantially increased over the last years (Mittal et al., 2017; Dulebenets, 2019). Such a trend can be explicated by different reasons, including increasing population, urbanization, and the existing needs to provide effective connections between different metropolitan areas. Passenger vehicles constitute the most popular mode of passenger travel in many countries. At least 80% of the hours of the day, vehicles generally spend in the parking mode (Marsden, 2006). In busy metropolitan areas that often experience congestion, parking space cruising (or parking search time) is considered as a significant part of the entire trip, except the cases when parking is reserved at the destination. Therefore, it is critical for local authorities to build a sufficient number of parking facilities with adequate capacity and in appropriate locations of a city to meet the growing demand and reduce the cruising time for parking space. Parking lots accommodate vehicles that arrive to their destinations for different purposes, including commercial, residential, industrial, shopping, entertainment, just to name a few. Many cities around the world use much of their valuable real-estate space in order to build new parking facilities, some of which have quite a substantial capacity. Table 1 shows a list of the largest parking lots in the world.

Note that the capacity of the parking lots that are listed in Table 1 may fluctuate from one year to another (e.g., additional parking spaces can be built to accommodate the demand). The West Edmonton Mall (Canada) has an enormous parking lot that is able to accommodate approximately 20,000 vehicles (DriveSpark, 2015). Some airports in the United States and Canada (such as Seattle-Tacoma International Airport, Detroit Airport, O'Hare International Airport, and Toronto Airport) also have high-capacity parking facilities, required for daily airport operations. All of these are single-purpose lots outside the city centers. In downtown areas, there are typically many smaller parking garages rather than one giant one, but even these smaller facilities can serve large numbers of customers. Due to significant parking demand in certain areas, local authorities or semi-private companies operating parking garages have to set high parking fees for on-street as well as off-street parking, especially in downtown areas of certain cities. New York (United States) is one of the cities that have prohibitively high fees for off-street parking. The average cost for 2-hour parking in New York reached approximately \$35 in 2019 – see Figure 1 (Parkopedia, 2019). Sydney (Australia), Brisbane (Australia), and Chicago (United States) are other examples of cities with parking fees that exceed \$20 for 2-hour parking in 2019.

By imposing high parking fees, local authorities are trying to encourage people to use alternative travel modes instead of passenger vehicles (e.g., use a subway to reach a destination instead of using a private vehicle and pay parking fees at the same destination). Otherwise, the existing parking capacity may not be sufficient to meet the demand, and local authorities would have to make sure that even more off-street parking facilities are provided. Building new parking facilities can be a challenge, especially in busy metropolitan areas, due to the cost and spacing constraints. Providing multistory underground parking spaces can be very expensive. The average cost of an underground parking space may vary from one city to another. Shoup (2014) reported that the average cost of an underground parking space in Honolulu (Hawaii, United States) may go up to ≈\$50,000, while the average cost of an underground parking space in San Francisco (California, United States) may go up to ≈\$40,000.

Along with meeting the growing demand for vehicle parking, local authorities as well as private businesses have to address some other issues that are associated with parking. Safety and security in parking lots are critical issues. Although travel speed is much lower in parking lots as compared to other facilities (e.g., interstates), accidents do happen in parking lots. In fact, thousands of pedestrians and cyclists are injured every year in parking lots around the world due to failure of drivers to detect them when

Table 1 The largest parking lots in the world

performing a parking maneuver. In some cases, pedestrians and cyclists may be at fault and cause accidents in parking lots due to lack of attention. Collisions between pedestrians/cyclists and vehicles in parking lots may even lead to fatalities. Furthermore, according to the U.S. Bureau of Justice Statistics (2020), more than one out of ten of all the property crimes are recorded in off-street garages or parking lots. Aggravated assaults, rapes, and murder may occur in parking lots of certain neighborhoods. In some parking lots, vehicles can be stolen. This chapter focuses on safety and security issues in parking lots. In particular, different parking maneuvers will be reviewed along with their safety implications. Moreover, a number of common parking challenges that may lead to certain safety and security concerns as well as various approaches for improving safety and security in parking lots will be discussed. Finally, concluding remarks regarding vehicle parking safety and security are provided at the end.

Parking Maneuvers

Three types of maneuvers exist for drivers in order to enter a given parking space, including the following (Findley et al., 2020): (1) pull-in; (2) back-in; and (3) pull-through. On the other hand, the following maneuvers can be used to exit a given parking space: (1) pull-out; (2) back-out; and (3) pull-through. The aforementioned parking maneuvers are illustrated in Figure 2. Based on the statistical data, collected by the American Automobile Association (AAA) for the year of 2015, approximately 11.6% of drivers in the United States back-into a parking space all the time or most of the time, while another 12.8% of drivers back-into a parking space frequently (AAA, 2015). The remaining drivers (approximately 75.6%) indicated that they rarely use the back-in maneuver for parking. Furthermore, male drivers are more likely to use the back-in maneuver for parking as compared to female drivers. However, the back-in maneuver is viewed as the safest parking maneuver (AAA, 2015; Findley et al., 2020).

Based on the information provided by the National Highway Traffic Safety Administration (NHTSA, 2008), there are almost 300 fatalities in the United States every year as a result of a nonoccupant (e.g., cyclist or pedestrian) being struck by a reversing vehicle (i. e., “backover” accidents as classified by the NHTSA). Moreover, more than 18,000 injuries are reported due to backover accidents,

Figure 2 Parking maneuvers: [A] - pull-in; [B] - back-in; [C] - pull-through; [D] - pull-out; [E] - back-out; [F] - pull-through.

which generally occur in nonresidential parking lots. The back-in maneuver can help preventing the backover accidents. In order to execute the back-in maneuver, a driver is required to pass the desired parking space, position the vehicle accordingly, and then start backing into that parking space. While performing the aforementioned steps, the driver will have an opportunity to clearly see the desired parking space and make sure that there are no other objects and obstacles. On the other hand, the drivers performing the backing-out maneuver may have challenges with the identification of moving vehicles, objects, and obstacles in the driving aisle. Pulling out of a parking space typically allows the driver to have a clearer view of the driving aisle, especially when driving a vehicle that is longer in the back as compared to the front (e.g., trucks, SUVs).

Drivers have to be attentive not only when performing the parking maneuvers but also when entering or exiting parking lots. Parking lot entrances in many countries have crosswalks used by pedestrians, especially in downtown areas of the cities. In the United States and many other countries, there are curb cuts at parking lots and even at single-family homes (e.g., the driveway entrance to the garage or parking area has a curb cut). This means that drivers can turn into their driveways at relatively high speeds without damaging the alignments of their vehicles. In many European countries, driveways not only to single-family homes but also to commercial businesses have a raised through sidewalk across the driveway, rather than a crosswalk, and drivers entering the driveway have a steep asphalt ramp to get up onto the sidewalk. This slows down the vehicles entering and crossing the pedestrian facility, improving the safety of not just pedestrians but also of bicyclists riding along the street.

Existing Parking Challenges

There exist a number of challenges associated with vehicle parking that may lead to certain safety and security issues. The key challenges of vehicle parking will be further discussed in this chapter, including the following: (1) vehicle parking policies and regulations; (2) parking space cruising impacts; (3) vehicle parking and cyclists; (4) vehicle parking and pedestrians; (5) vehicle parking and older adults; and (6) automation impacts on vehicle parking.

Vehicle Parking Policies and Regulations

Marsden (2006) highlights that parking policies can be considered as the key link between land-use policies and transport. Parking policies have to support the major objectives of vehicle parking, including the following: (1) restraint; (2) regeneration; and (3) revenue. The aforementioned objectives can be viewed as conflicting in their nature. For example, the revenue, generated from vehicle parking facilities, contributes to the prosperity of cities. Increasing capacity of parking facilities can be used as a means of regenerating certain areas of cities. On the other hand, the attractiveness of city centers could be negatively affected with desert-like huge parking lots and lack of walkability, so parking facilities need to be kept attractive and have limited footprints on the ground level. However, the introduction of parking restraint measures may have even more negative effects on commerce. When it comes to parking restraint policies, drivers making shopping and leisure trips generally have more flexibility as compared to commuters, as they can adjust the frequency of visits and, ultimately, change their destination (Marsden, 2006).

The out-of-pocket costs (including the costs that are associated with parking fees) and walking time are recognized to be more important to drivers when comparing to in-vehicle costs. Many drivers are still willing to walk fairly long distances from free parking spaces to their respective destinations, despite the sensitivity of drivers to increasing walking time. In some cases, drivers may be willing to pay higher parking fees and select the parking spaces that are close to the destination when walking time becomes excessive. In many jurisdictions, including the United States that has the Americans with Disabilities Act (ADA) legislation, people with disabilities are often given free parking spaces that are located close to potential destinations. Furthermore, parking policies should be developed considering the fact that parking fees may actually prompt users switching from a private car to alternative modes of transportation (e.g., transit). Trip purpose, income level, travel distance, vehicle type, number of return trip stops, age, and gender are found to be significant factors that may influence mode choice under different parking fee options (Tsamboulas, 2001). Parking policies must be designed, considering local spatial and transport planning processes, to support strong and vibrant economy, ensure clean urban environment, provide good accessibility, enable safe and secure environment, and support more equitable society (Marsden, 2006). The safety issues should be adequately addressed by parking policing, taking into account high occupancy of parking spaces (especially in residential areas) that reduces the number of crossing points for pedestrians.

Parking Space Cruising Impacts

Parking space cruising may become a challenge, especially in large metropolitan areas. Off-street parking spaces (e.g., parking in dedicated garages) are often available to drivers immediately; however, they are not free and drivers are required to pay parking fees. On the other hand, curb parking can be either low-cost or completely free but cruising for such parking spaces may require significant time, as the number of available curb parking spaces is generally limited, especially during certain time periods (e.g., peak hours, weekends, particular events). Many drivers are not willing to pay for off-street parking spaces, if they can find free parking. If all the curb parking spaces are occupied by vehicles at a given moment, some drivers are willing to continue cruising until one of the occupied spaces is vacated. Typically, drivers choose cruising in case off-street parking is significantly more expensive than curb parking, fuel is cheap, parking duration is fairly long, vehicle occupancy is low, and the cost of time is fairly low (Shoup, 2006). However, cruising can be completely eliminated by imposing high parking fees for curb parking spaces (e.g., approximately equal to off-street parking fees).

Moreover, excessive cruising may result in negative externalities, including pollution of cities, increasing fuel consumption, traffic bottlenecks, and increasing accident rates. During peak hours in downtown areas of certain cities, a substantial portion of traffic is composed of drivers who are cruising for curb parking; thereby, causing congestion and increasing the risk of accidents. It can take up to 14 minutes to find a curb parking space in congested downtown areas (Shoup, 2006). Therefore, local authorities have to set the appropriate parking fees for curb parking to prevent excessive cruising of drivers that may further lead to safety concerns. Increasing curb-parking fees would prompt a certain portion of drivers using off-street parking facilities.

Vehicle Parking and Cyclists

The number of bike lanes has been increasing over the past years in many cities, especially in North America. Bicycling is encouraged around the world. Many of industrialized countries have moved away from bike lanes and provide bike tracks between the sidewalk and automobile lanes, with parking being between the travel lane and the bike track. However, a significant portion of bike lanes on urban arterials still have adjacent on-street parking spaces, and vehicles are required to cross the bike lane before entering the on-street parking spaces. As indicated earlier, the vehicles that are backing out from their parking spaces present a potential hazard for cyclists. Along with backover accidents, there are some other safety issues for cyclists that can be caused by parked vehicles (see Figure 3). "Dooring accidents" that involve opening car doors and cyclists are observed quite often in certain cities and

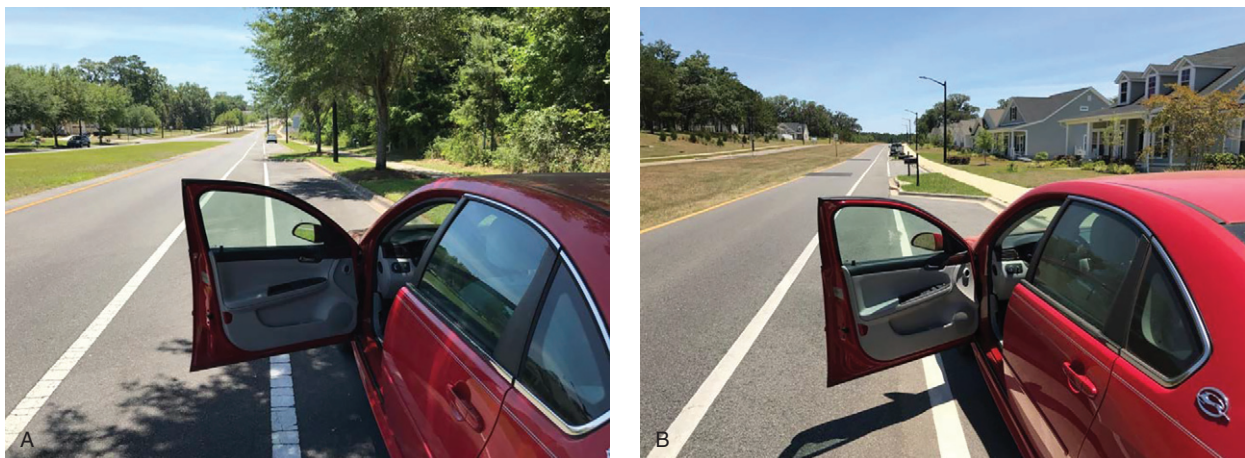

Figure 3 A bike lane adjacent to curb parking (Tallahassee, Florida, USA): (left) - Four Oaks Boulevard; (right) - Orange Avenue East.

comprise a significant percentage of cyclist-motor vehicle accidents (Schimek, 2018). Different cyclist organizations along with government agencies keep warning cyclists regarding suddenly opened doors of parked vehicles, even if cyclists are strictly using dedicated bike lanes. Nevertheless, dooring accidents continue occurring every year. Various types of injuries can be caused by dooring accidents. The cyclist can have a cutting injury after colliding with a sharp edge of the opening door. The cyclist can break the door window glass after collision at a full speed. In many cases, cyclists fall on the ground after colliding with suddenly opened doors, which further causes injuries from hitting the asphalt. Certain dooring accidents may even result in fatalities when cyclists fall in the direction of approaching vehicles, as drivers of approaching vehicles may have a very limited time to react.

The safety issues of cyclists can be addressed by increasing the bike lane width. When the minimum bike lane width standards are used, cyclists generally have to ride in the range of opening doors. However, most of the cyclists tend to ride outside of the range of opening doors after creating an additional buffer space of 3–4 feet ($\approx 0.91\text{--}1.22\text{ m}$) between the bike lane and parked vehicles. Some countries started incorporating the buffer space for bike lanes to capture the door zone in their design guidelines (e.g., North America); however, many countries are still using the minimum bike lane width standards (Schimek, 2018). Furthermore, regulations in certain countries require vehicle occupants to look around before opening the doors of a vehicle after parking. Opening doors is permitted only when it is safe to do so. Many safety guidelines also encourage cyclists to stay away from the doors of parked vehicles and use additional precautions when passing parked vehicles (e.g., reduce travel speed, so there will be more time to react in case of a suddenly opened door).

Vehicle Parking and Pedestrians

Backover accidents (i.e., a pedestrian is struck by a reversing vehicle) are one of the major safety concerns for pedestrians in parking lots. There may be different causes of backover accidents involving pedestrians. Pedestrians may not realize that a vehicle is trying to leave the parking space and walk behind a reversing vehicle. As discussed earlier, the backing-out maneuver may cause challenges for a driver with the identification of pedestrians approaching from the driving aisle. A substantial portion of backover accidents involves children (Rouse and Schwebel, 2019). The involvement of children in certain backover accidents can be explained by the fact that children may not understand the meaning of reverse lights and continue moving in the direction of a reversing vehicle. Furthermore, a driver, performing the backing-out maneuver, will have more difficulties to see children as compared to other groups of pedestrians due to the short stature of children. In some cases, children may get injured in backover accidents due to lack of adult supervision. Without constant adult supervision and guidance, many children can create risky situations in parking lots. In the meantime, young children lack certain important cognitive skills (e.g., attention and concentration), which are necessary for safe pedestrian behavior. Along with young children, older pedestrians also suffer from lack of cognitive skills that may result in backover accidents.

In order to reduce the number of backover accidents in parking lots, vehicle-manufacturing companies started installing advanced technologies in their vehicles. Rear cross-traffic alert systems, rear-view cameras, and automatic braking are some of the common technologies that are used in modern vehicles to assist drivers with safer backing decisions and prevent collisions with pedestrians (Findley et al., 2020). Many newer vehicles have rear cross-traffic alert systems that use sensors to detect objects (e.g., cyclists, pedestrians, other vehicles) that are approaching from the areas that are difficult to notice in the direction of a reversing vehicle. Once the approaching object is detected, visual alerts, audio alerts, and even automatic brakes will be applied. Rear-view cameras can be also used to identify objects when performing the backing out parking maneuver. New technologies generally provide some safety improvements when performing parking maneuvers. Nevertheless, these intelligent technologies have to be continuously tested and modified to improve their accuracy. For example, rear-view cameras show a quite poor performance under inclement weather conditions, whereas rear cross-traffic alert systems fail to detect approaching cyclists, pedestrians, and other vehicles from time to time. Also, drivers may fail to look at the monitor, so it can be helpful to combine the camera system with an audible signal, activated only when there seems to be an object behind the vehicle.

Vehicle Parking and Older Adults

Older adults typically drive less than their younger counterparts but are still required to make parking maneuvers at the end of their trips. Different sociodemographic characteristics of individuals, such as age, gender, socioeconomic belonging, driving experience, and health conditions, may substantially impact their driving and parking abilities. Age-related changes in physiological functions of individuals (i.e., hearing, vision, coordination, perception, cognition, and reaction) may cause challenges when cruising for parking space and performing various parking maneuvers in parking lots. Older adults generally have poor useful field of view and are not able to effectively identify surrounding objects, including approaching vehicles. Moreover, some older adults have a tendency of returning to the areas that have been already visually searched, which significantly slows down the speed of processing certain important information while driving. Impaired cognitive and psychomotor skills can also lead to accidents and driving violations under normal driving conditions and disruptive driving conditions (e.g., inclement weather, rush-hour traffic). Furthermore, the presence of chronic diseases (e.g., heart diseases, diabetes, dementia, Alzheimer's disease, arthritis) generally increases mental demand of older adults while performing different driving maneuvers and increases the risk of colliding with other vehicles or pedestrians.

There are different types of aberrant parking behavior that are common for older adults, including lapses, slips, anticipation errors, execution errors, and violations (Douissembekov et al., 2014). Lapses correspond to missed actions and omissions during

parking, while slips are associated with the actions that are not performed as originally planned. Anticipation errors are generally caused by lack of attention while seeking for parking space (e.g., failure to notice the vehicles leaving their parking spaces and creating room for other vehicles). Execution errors correspond to the errors that occur throughout execution of parking maneuvers. Violations represent parking actions that may lead to some legal issues. Lapses, slips, and execution errors can be explained by the declining ability of older adults to effectively survey the environment for surrounding objects and obstacles. As for anticipation errors, older adults may have difficulties noticing the presence of other drivers and anticipating their actions in parking lots. Moreover, despite the fact that older adults generally take more time to perform driving maneuvers (including parking), some of these maneuvers can be quite risky or even illegal.

Automation Impacts on Vehicle Parking

As indicated earlier, parking demand has been increasing over the years, and there is a need to better manage the existing parking space and accommodate the demand. One of the approaches to improve utilization of vehicle parking facilities is deployment of autonomous vehicles. Unlike conventional vehicles, autonomous vehicles do not require drivers and passengers to be present inside the vehicles in parking lots and perform parking maneuvers (Nourinejad et al., 2018). Drivers and passengers can exit autonomous vehicles at the entrance to a parking facility or near the designated drop-off area. The autonomous vehicle parking systems are expected to accommodate more vehicles, as the driving lanes can be narrower, elevators and staircases that are generally used by passengers can be completely removed, and the additional room that is used for opening vehicle doors will not be necessary anymore. The parking space utilization in parking facilities can be increased by parking autonomous vehicles in several rows. Typical layout examples of conventional and autonomous vehicle parking facilities are presented in Figure 4 and Figure 5.

Along with improved parking space utilization, autonomous parking has some safety benefits for passengers as well. In fact, no drivers and passengers will be present inside autonomous vehicles while these vehicles perform parking maneuvers, which eliminates the possibility of passengers being injured during parking. Moreover, since no passengers will be walking in autonomous parking lots (except the designated pick-up and drop-off areas), the possibility of backover accidents can be eliminated. However, there are some challenges with using autonomous vehicle parking facilities. In particular, an autonomous vehicle that is required to leave a parking facility may be surrounded by other vehicles (i.e., “barricaded” or “blocked” by other vehicles), and some of the parked vehicles have to be relocated in order to create the required room for the leaving vehicle (see Figure 5). This is a similar issue

Figure 4 Conventional vehicle parking facility.

Figure 5 Autonomous vehicle parking facility.

as that of stacked parking, which has been used for decades in some big cities (e.g., New York, United States). But the number of such parking facilities is not significant, and these facilities are generally managed by attendants. Autonomous parking systems may soon be standard around the world even in smaller towns. Therefore, advanced decision support systems are required to allocate the appropriate parking spaces in autonomous vehicle parking facilities. Ideally, the number of parking rows should be increased in autonomous vehicle parking facilities to improve the parking space utilization. In the meantime, the number of vehicle relocation moves should be minimized, so passengers will not have to wait for their vehicle to exit the parking facility for an extended period of time. Moreover, some special design considerations should be given to the parking facilities that serve both conventional and autonomous vehicle types.

Concluding Remarks

The demand for passenger and freight transportation has been growing in later years, even if the 2020 pandemic temporarily has halted this development. Passenger vehicles are the most popular mode of passenger travel. At the end of each trip, a driver is required to find a parking space. Considering an increasing demand for vehicle parking, local authorities of many cities have made significant investments into large parking facilities, some of which have quite a substantial capacity. Safety and security remain some of the most important issues in parking lots. Thousands of pedestrians and cyclists are injured every year in parking lots as a result of backover accidents. These accidents are primarily caused by the inability of drivers to detect approaching objects and lack of attention from pedestrians and cyclists. The number of backover accidents can be reduced if drivers start using alternative parking maneuvers (e.g., pull-out or pull-through). Many cyclists in certain cities are injured from dooring accidents that are caused by suddenly opened vehicle doors. Dooring accidents can be prevented by additional precaution measures from drivers and cyclists. Moreover, creating a buffer space between bike lanes and parked vehicles serves as an effective countermeasure against dooring accidents. The bike lane can be even relocated on the other side of the parking lane, next to the sidewalk, to effectively reduce the number of dooring accidents. Drivers are required to be more attentive when performing parking maneuvers if they see young children or older pedestrians. Due to lack of cognitive skills, young children and older pedestrians may cause risky situations in parking lots.

Some parking safety and security issues can be alleviated through the implementation of effective policies. For example, by imposing appropriate fees for curb parking spaces local authorities can reduce or even completely eliminate excessive cruising for curb parking, as excessive cruising may lead to traffic congestion and increase the risk of accidents. Furthermore, deployment of autonomous vehicles is expected to improve safety in parking lots, since no drivers and passengers will be present inside autonomous vehicles while these vehicles perform parking maneuvers. There will be no passengers walking in autonomous parking lots (except the designated pick-up and drop-off areas), which will eliminate the possibility of backover accidents. Many vehicle-manufacturing companies started installing advanced technologies (e.g., rear cross-traffic alert systems, rear-view cameras, and automatic braking) in their vehicles in order to reduce the number of accidents in parking lots. These technologies allow detecting the objects that approach in the direction of a reversing vehicle and preventing backover accidents in many cases. However, intelligent parking technologies still should be further tested and modified to improve their accuracy.

Biography

Maxim A. Dulebenets, PhD, PE is an Assistant Professor in the Department of Civil & Environmental Engineering at Florida A&M University-Florida State University (FAMU-FSU) College of Engineering. Dr. Dulebenets holds BSc and MSc degrees in Railway Construction from the Moscow State University of Railroad Engineering (Moscow, Russia), and MSc and PhD degrees from the University of Memphis (Memphis, TN, USA) in Civil Engineering. His research interests include, but are not limited to, operations research, optimization, simulation modeling, meta-heuristics, transportation engineering, and safety. Dr. Dulebenets has been involved in a variety of research projects with the overall value of ~\$5.4 million (~\$1.2 million as a Principal Investigator), sponsored by different public and private agencies, such as the United States Department of Transportation, National Science Foundation, Center for Accessibility and Safety for an Aging Population, and Florida Department of Transportation. He serves as a referee for 60+ international journals, including European Journal of Operational Research, International Journal of Production Economics, IEEE Transactions on Intelligent Transportation Systems, and Computers & Operational Research. Dr. Dulebenets is an Invited Member of the Standing Committee on International Trade and Transportation (AT020) of the Transportation Research Board of the National Academies of Sciences, Engineering, and Medicine (USA). Furthermore, Dr. Dulebenets is an Affiliated Member of the Institute for Operations Research and the Management Sciences (INFORMS) and the Institute of Electrical and Electronics Engineers (IEEE).

Introduction

Passenger vans are medium-sized vehicles that are larger than passenger cars but smaller than buses. In this paper, the term passenger van, as generally used in North America, refers to vehicles with the seating capacity of 12–15 people, which are primarily used for transporting passengers. In other countries, passenger vans are sometimes known as minibuses, such as in Australia and New Zealand, and minibus taxis in South Africa. Vans are widely used and known as “colectivos” or shared buses/taxis in several Latin American countries.

There is a wide range of designs and body configurations of passenger vans in different countries, but most have a carrying capacity between 10 and 15 seats. Van dimensions are typically 5–6 m in length, 1.6–2 m in width, and 2–2.3 m in height. Seating arrangements also vary, but most have three to five rows of seats, with one or two passenger seats in the same row as the driver's seat, and three to four seats per row in the rows behind the driver's seat. In the passenger areas, seats in the front part are usually arranged to allow space on one side of the van for passenger movement while boarding and alighting the vans. A sliding door on this side is common, although some models have swing doors or have doors on both sides of the vehicles. The rear part of passenger vans usually has a small space for cargo storage, and a set of barn doors, which are hinged on the side or a tailgate door, which is hinged on the top. Smaller vans, with seven to eight seats, are usually referred to as minivans.

Use

Although in many countries vans are still used primarily for transporting goods, passenger vans were developed in the 1970s to cater to a group of people traveling together for various purposes, including work commute, business, recreation, and school. Since then, passenger vans have become increasingly popular in many parts of the world, due to its versatility, maneuverability, and relatively low costs. According to the National Transportation Safety Board, as many as 500,000 15-passenger vans are currently in use in the United States alone (Subramanian, 2004).

Passenger vans are used for a wide range of trip purposes, including private, commercial, and institutional activities. They are often used for school and office trips and shuttle services. People can also rent them for family and group tours in tourist destinations. Van rental services are widely available in North America, Europe, and other popular locations around the world.

In a number of developing countries, passenger vans are used for public transportation, often operated by informal owner-operators, due to lower investment costs compared with buses (Behrens et al., 2015). For example, in South Africa, minibus taxis play a major role in the country's public transport system. The South African National Taxi Council estimated in March 2017 that there were more than 200,000 minibus taxis in the country. In other African countries, passenger vans are widely used as share taxis and are known by local names, such as HiAce (Cape Verde), Matatus (Kenya), and Tro Tro (Ghana). In Thailand, approximately 15,000 passenger vans provide local and intercity public transport services, and 21,000 passenger vans are used for chartered services in 2019.

Even in developed countries, passenger van operators in some cities provide commuter services in areas with limited conventional public transport services. For instance, in the New York metropolitan areas, “dollar vans” serve a number of areas with limited subway services, particularly in low-income, immigrant communities. In Miami, Florida, passenger vans, known locally as “jitneys,” have long provided paratransit services in areas not served by buses and Metrorail.

Passenger van services range widely from ones with fixed routes, fixed stops, and fixed schedules to those without anything fixed. The level of service flexibility largely depends on the regulatory context of the city in which they operate. For example, in New Zealand, passenger vans are allowed to provide commercial service with one end of the trip ending at transport stations, such as railway stations, airports, or ferry terminals. Passenger vans are thus classified as commercial vehicles and must conform to public transport regulations including vehicle standards and driver’s qualification. In New York City and Miami, the van services generally operate on a generally fixed-route and fixed-stop basis, but they do not usually follow a fixed schedule. In South Africa, passenger vans provide services in both fixed and unfixed routes, and most, if not all, of them do not operate on a fixed-stop and fixed-schedule basis (Behrens et al., 2015). This is also the case in Thailand. Passenger vans are also available for chartered service and rental in several countries.

Passenger van services are often characterized by informality in that the operations are not initiated, supported, and, at least at the beginning, regulated by the government. They sometimes compete directly with buses and other public transport, but then they also provide complimentary services to the conventional public transport systems, serving as feeder modes in areas where the conventional modes are unavailable or as on-demand paratransit service for mobility-impaired persons. In Thailand, van operations were mostly informal at the beginning in the 1990s, but they are now systematically organized and regulated by the government. In New York City and Miami, the dollar van and jitney operations are heavily regulated by the city governments.

Accident Statistics

Van crash statistics vary among different countries. In the United Kingdom, according to the Department for Transport, between 2006 and 2015, the rates for fatality and serious injury per billion passenger-kilometers among vans (54) are much lower than cars (208) and motorcycles (4,018) (UK Department for Transport, 2017). In the United States, between 1995 and 2001, the rate of fatal single-vehicle crashes per 100,000 registered vehicles with 15-passenger vans (15.6) is substantially higher than cars (8.7), pick-up trucks (11.9), and SUVs (13.3), although the rate has steadily been decreasing (Subramanian, 2004). In Thailand, the number of fatal injuries involving motorcycles and cars far exceeds those of passenger vans, in general. However, passenger vans used for public transport purpose are notoriously unsafe compared with other types of vehicles. According to the Department of Land Transport, in 2017, despite the relatively small number of passenger vans registered in Thailand (41,202), there were 252 passenger van accidents, with 135 fatalities and 1,046 serious injuries in Thailand. The accident statistics improved significantly in 2018 thanks to the government’s required installation of GPS tracking devices, which discourage speeding and reckless driving behavior.

Similarly, in South Africa, a total of 70,000 minibus taxi crashes occur annually, according to a study by the Automobile Association of South Africa. Although minibus taxis account for only 4.5% of the total number of passenger vehicles, they are reportedly involved in 8.6% of all crashes in 2001. Almost 10% of road traffic fatalities in the country involve minibus taxi-related accidents.

The most common passenger van accidents include single-vehicle crashes, rollover crashes, and tire blowouts. In the United States, a significant proportion of fatal accidents have been found to be associated with rollovers caused by tire failures. Statistics show that half of fatalities in passenger van accidents occurred in heavily loaded vans that rolled over. The high risk of rollover crashes and tire failures in passenger vans has been attributed to the vehicles’ higher center of gravity, and consequently instability, especially when fully loaded (Potter et al., 2013). The frequency and severity of passenger van accidents may also be caused in part by the driver’s lack of training and experience in maneuvering properly in response to incidents, such as fishtailing or tire blowouts. Also, a substantial proportion (70%) of fatalities to passenger vans’ occupants have been associated with those who were ejected from the vehicles, prompting the US federal authority to issue recommendations to state authorities to revise the law to mandate safety-belt use among passenger van occupants. Recent statistics show that fatalities to van passengers have declined steadily, probably due to the awareness of van safety issues as promoted by the authorities (Subramanian, 2008). However, critics argue that the downward trend in passenger vans’ accident statistics was caused by a decrease in the use of passenger vans, rather than improvements in safety standards.

The accident risk exposure of different uses of passenger vans varies. For example, due to lower amount of mileage driven and relatively infrequent use, the risk exposure of passenger vans used for private purposes is likely to be lower than that of passenger vans used for institutional and commercial purposes, and those in public transport services. Passenger vans used for intercity public transport services, especially those on long-distance routes, are more prone to accidents than those used for urban transport services. Moreover, passenger vans in chartered services are more prone to accident than those in fixed route services since chartered van drivers tend to be less familiar with the roadway environment than those of fixed route services. For these reasons, analyses of accident statistics involving passenger vans must take such factors into account. In Thailand, for example, a study by the Department of Land Transport shows that the annual rates of fatalities per 10,000 vehicles in 2015 are 19 and 40 for passenger vans in urban and intercity routes, respectively. Likewise, the rates of serious injuries per 10,000 vehicles are 132 and 354 for passenger vans in urban and intercity routes, respectively. Therefore, measures to prevent accidents involving passenger vans must be tailored according to the vehicle’s purpose of use. Unfortunately, accident statistics by purpose in many countries are not readily available.

Factors Affecting Passenger Van Safety

Analyses of accident statistics of passenger vans in many countries show that the accident risk and severity of accidents can be attributed primarily to vehicle- and human-related factors. Vehicle-related factors include design problems, the way in which the vehicles are loaded, and roadworthiness of the vehicles. Human-related factors include the driver's skill in responding to incidents, the driver's attention and alertness, and passengers' use of restraint equipment. These factors may be interrelated. For example, due to design problems in some models, passenger vans' instability may require that drivers possess certain driving and correction skills so that potential accidents can be avoided.

Van drivers' behaviors that affect safety may also depend on the incentive structure in which they operate. For example, the low-cost nature of passenger vans also means that the vehicles can be cheaply acquired and used for providing public transport services in countries where regulations are lax. Without proper safety inspection and enforcement of traffic rules, passenger vans may be driven recklessly at high speed by small, owner-operated businesses making them prone to serious accidents. Drivers may also work for longer hours in order to earn more fare revenues, causing fatigue, and may fall asleep behind the wheel. In this section, each factor that causes safety concerns of passenger vans are discussed in turn.

Vehicle Design

Several design problems in some passenger van models are cited as causes of passenger van's poor safety records. First, due to the vehicle's length, some van models are more prone than others to fishtailing, especially when fully loaded. Second, vans can be unstable where there are crosswinds due to the vehicles' flat sides. Third, some van models have relatively short or no crumple zones, and provide little protection to occupants in the front part of the vehicles in the event of head-on collisions. Fourth, seating arrangements and the lack of escape doors in some van models may also prevent timely evacuation of occupants in the event of a stuck or damaged sliding door. Fifth, uneven distribution of load on tires on different sides of the vehicle due to unbalanced seating arrangement increases likelihood of blowouts if the tires are worn or not properly inflated. Finally, due to the high center of gravity of passenger vans, the vehicle's stability tends to be poor, posing greater risk of a rollover accident. The problem of high center of gravity is especially severe when vans are fully load or when vans are modified, such as the installation of a compressed natural gas fuel tank, which is common in some countries.

Vehicle Safety Tests

Various safety aspects of passenger vans have been tested by New Car Assessment Programs (NCAP) in different regions. For example, Euro NCAP conducted crash tests of several passenger van models, and recommended that since passenger van design is derived from commercial vans, its safety features are not updated as regularly as passenger cars or sedans, so van manufacturers should improve safety features of the vehicles more regularly. Toyota HiAce, the passenger van model that is most widely used in Thailand, has been tested by Australasian NCAP, and the result shows relatively poor passenger protection in frontal impacts.

Vehicle's Maintenance and Inspection

In addition to design problems, van safety concerns may result from poor vehicle maintenance. In developing countries where passenger vans are used for informal public transport services and official vehicle inspections are lax, operators may skip routine maintenance to save costs, resulting in unsafe vehicle conditions.

Driving Skills

Drivers' handling of passenger vans can also increase the risk of accidents. As fully loaded and lightly loaded vans handle much differently, faced with instability while driving fully loaded vans and fishtailing, drivers who are unfamiliar with passenger vans may overcorrect the steering, thereby increasing the risk of a rollover. Drivers who are not familiar with passenger vans may also not know the proper tire pressure and fail to inflate rear tires properly, thereby increasing the risk of blowouts. In developing countries where vans are used as public transport vehicles, van drivers' behavior significantly increases the risk of van accidents. Due to the vehicle's relatively small size and maneuverability compared to larger public transport vehicles, van drivers can drive at higher speed and make abrupt adjustment in directions. Where public safety regulations are loosely enforced, unsafe driving practices by passenger van drivers can translate into higher risk of accidents.

Driver's Behaviors

Inappropriate behaviors of drivers and passengers also contribute to poor safety records of passenger vans, especially in developing countries where law enforcement is lax. Due to its relatively small size, it is quite easy for van drivers to use high speed, exposing the vehicles to severe crash risks. Fare revenue incentives also induce other risky behaviors other than speeding, such as overloading of passengers, modification of seats to load more passengers than design capacity, as well as working longer hours than allowed, causing fatigue. Failure of passengers to use safety belts also contributes to serious injuries or fatalities when accidents occur.

Policy Initiatives, Safety Precautions, and Recommendations

General Safety Precautions

Due to poor safety records, governments have increasingly regulated passenger vans' operation. In the United States and Canada, transport agencies have repeatedly issued cautionary warnings about passenger van safety. The National Highway Traffic Safety Administration (NHTSA), the US safety authority, recommends specific precautions regarding the use of passenger vans, including experiences of drivers, ensuring appropriate tire pressure, seating of passenger to avoid unbalanced load, use of seat belts by all passengers, and prohibition of carrying cargo on the roof. Since the low rates of seat-belt usage among passengers of vans involved in fatal crashes were attributed to the fact that vans are treated as buses and hence passengers are not required to wear safety belts, the authority also recommended that state laws regarding mandatory use of seat belts be revised to include passenger vans.

Safety Regulations in Passenger Vans Used for Public Transport

In countries where passenger vans are used for public transport services, the government has also implemented several policy initiatives to improve the poor safety records of passenger vans. In South Africa, the national government has implemented the Taxi Recapitalization Program since 2000, which aims to replace old passenger vans with new purpose-built 18- and 35-seater vehicles (Behrens et al., 2015). In Thailand, serious van accidents prompted the government to phase out passenger vans for public transport use, starting in 2017. For those vans that are still in use for public transport services, some modifications of the vehicles are required, including the removal of some seats in the last row to allow escape in the event of an accident and to limit the number of passengers to 13 for intercity services. Installations of safety equipment such as safety belts for all seats, emergency hammer window breakers, fire extinguishers, as well as GPS tracking are also mandated for all passenger vans. However, at the time of writing, it remains unclear whether these initiatives are successful in curbing passenger van accidents and injuries.

When passenger vans are used for public transport, accidents are often caused by drivers' reckless driving behaviors and fatigue. The standard punitive responses are to fine or arrest individual drivers for violating traffic regulations, and to have their licenses suspended or revoked. But drivers' behaviors and exhaustion could be attributed to the underlying incentive structure of the business and operational models (Ratanawaraha and Chalermpong, 2018). Because passenger-van services are usually operated with little or no financial support from the government, the drivers are often without adequate salaries and social benefits. As their income depends on the number of passengers and trips, they are thus incentivized to work long hours and drive fast (Sinclair and Imaniranz, 2015). Such behaviors increase safety risks on the road. Compensation levels and methods should therefore be carefully determined in such a way that increases operational efficiency without compromising safety.

The business models are shaped by the way in which the government allocates the rights and routes to operate van services. Some licensing schemes allow open competition among operators of vans and other modes of public transport (Chalermpong et al., 2016). This often results in cutthroat, on-the-road competition on lucrative routes in high demand and an increase in safety risks, while leaving unserved other routes in low demand.

Setting and enforcing traffic and drivers' standards is one policy option to deal with safety risks associated with van drivers. In many cities, drivers of passenger vans are required to take specific safety training courses and to acquire professional/commercial driver's licenses. For instance, jitney operators in Miami are required to obtain a Passenger Motor Carrier Certificate of Transportation, while drivers must have a for-hire chauffeur registration and must attend specific training programs conducted by the For-Hire Transportation section of the Business Affairs Division. Drivers' eligibility qualifications include driving record and criminal background checks, as well as mandatory participation in drivers' training programs. The vehicles themselves are required to obtain inspection and operating permit decals issued by the Vehicle Inspection Station. Similar regulations are also applicable to dollar-van operators in the New York metropolitan areas, as well as in cities in developing countries. But the rigor with which they are enforced varies from place to place.

Another policy option is to adopt the chain-of-responsibility approach to regulating passenger van services. The basic idea is that, because each party in the transport supply chain assumes different levels of responsibility in creating and managing safety risks, they should also be held accountable differently. Accordingly, legal obligations and penalties are placed not only on the drivers themselves but also on the licensees who acquire the right to operate from the government. In the case of New York City, when an individual van driver violates a traffic rule or an operational requirement, that violation is counted cumulatively for a certain time period and also collectively for the whole group that operates under the same license.

Biographies

Saksith Chalermpong is associate professor in the Department of Civil Engineering at Chulalongkorn University, Bangkok, Thailand. He currently serves as Deputy Director of Chulalongkorn University Transportation Institute. He was a visiting researcher at Kyoto University Center for Southeast Asian Studies. His research interests include urban transportation planning and policy, public and informal transportation, and equality issues in transportation policy. He received his bachelor's degree in civil engineering from Chulalongkorn University, his master's degree from MIT, and his doctoral degree from UC Irvine, both in the field of transportation.

Apiwat Ratanawaraha is associate professor in the Department of Urban and Regional Planning, and an advisor at the Urban Design and Development Center, both at Chulalongkorn University in Bangkok, Thailand. He is specialized in urban planning and development, infrastructure finance, technology and innovation policy, and futures studies. His ongoing and recent research includes projects on the futures of urban life in Thailand, the futures of clubs and commons, globalization of land, urban citizen science, and informal mobility in Thailand. He was a visiting assistant professor at the MIT Department of Urban Studies and Planning, and a visiting scholar at the Harvard-Yenching Institute, Cambridge, MA.

Automobile Safety

Automobile safety has improved immensely in recent decades. The World Health Organization (WHO) reports that casualty numbers due to road traffic incidents are still huge; globally, 1.35 million people die and 50 million are injured in road traffic incidents every year (WHO, 2018). That is nearly 3,700 fatalities and nearly 137,000 injuries every day. Policies and laws are reasonably similar in most countries. However, law enforcement and awareness vary a great deal, often with the socioeconomic status and cultural values of the countries. The number of casualties is far greater in poorer or developing countries than in the most developed countries.

Automobile traffic accidents have happened for as long as the automobile has been around (Fig. 1). Road safety can improve through a variety of approaches. Potential incidents and casualties can be predicted and prevented in certain conditions. Road structure, such as the quality of the road or road furniture, and human factors, such as driver behavior, are important subsystems of the road safety system. Designers and manufacturers in the automotive industry continuously use the latest technology and accumulated knowledge to improve active and passive safety systems to make safer vehicles to balance the complex transport safety system. Legislation is passed and enforced by governments, and organizations try to raise awareness for public safety. The focus of this article is passive safety.

Passive safety systems aim to minimize the severity of injuries and the number of fatalities during the collision when it happens. On the contrary, active safety systems seek to avoid collisions in the first place. For example, anti-lock braking systems or electronic stability control are well-known, mature active safety systems. However, they are still not standard in automobiles in many countries. Unfortunately, even in the countries where sophisticated active safety systems are mandatory in most automobile models, accidents still happen. Therefore, reliable passive safety systems in vehicles are extremely important and will always be needed.

Some passive safety systems, such as installation of seat belts, are mandatory, and some are optional depending on automobile models and where in the world they have been manufactured, sold, or registered. The US New Car Assessment Program (NCAP) provides a five-star safety rating scheme and consumer information on new cars since 1979. Similar programs, with slightly different protocols, have been set up on other continents with extensive tests taking place in independent crash test laboratories; and new vehicles are graded according to their performance in protecting their occupants in Europe, Latin America countries, South Asian countries, Australasian countries, Japan, Korea, and China, respectively, by Euro NCAP, Latin NCAP, ASEAN NCAP, ANCAP, JNCAP, KNCAP, and C-NCAP.

The following sections cover the importance, brief history, working principles, and usage of passive safety systems, namely, seat belts, airbags, head restraints, child seats, laminated and tempered safety glass for windows, crumple zones and safety cells, collapsible steering columns, and other effective passive safety measures.

Seat Belts

Using seat belts is a highly effective passive safety method of preventing serious injuries and fatalities in automobiles. They are designed to secure the driver or passengers to a stationary object in the vehicle to protect them from sudden deceleration or stop as a

Figure 1 Motor vehicle traffic accidents have happened for as long as automobiles have been around.

result of a collision. As a body would continue to move forward within the car during deceleration of the vehicle, seat belts help to avoid the occupants from being ejected from the vehicle. Importantly they also prevent the occupants from hitting the vehicle interior and each other within the vehicle. A correctly worn seat belt also helps the occupant to take maximum advantage of other restraint systems such as airbags and head restraints.

There is evidence that vehicle seat belts were invented and used in the 19th century by a mechanical engineer George Cayley to protect his coach driver taking part in flying experiments with his glider designs. It is difficult to identify the person who first “thought about” automobile seat belts. Patents filed in 1855 and 1903 by Edward J. Claghorn and Gustave-Desire Leveauto, respectively, describe belts resembling two-point seat belts to secure people to fixed objects. An article written in 1955 by Hunter Shelden, a neuroscientist, defends prevention as the only cure for head injuries, and suggests retractable seat belts amongst other safety systems such as door locks and airbags (Shelden, 1955). Griswold and DeHaven’s seat-belt idea about a combination of lap and shoulder safety belts to restrain the occupants was patented in 1955. The three-point seat-belt design, which is in principle not very different to the seat belts that automobile occupants use today, was patented by Nils Bohlin 60 years ago (in 1959) while he was working as a mechanical engineer for Volvo (Fig. 2). He had refined the idea of restraining the occupant by a shoulder belt diagonally across the chest and a lap belt across the hip bones with a simple V-shaped design which did not move under load, and, from 1959 on, it became standard in some Volvo models on the Nordic markets. Volvo almost immediately opened up the three-point seat-belt patent to all car manufacturers.

Further developments over the years have not changed the main design but improved comfort. For example, including retractors provides convenience of easy size adjustment and gives occupants reasonable freedom of movement during the journey, whereas a sudden deceleration immediately locks the seat belt and fixes the position of the occupant. Advancement in technology is also reflected in seat belts. Pretensioners are used to preemptively limit the movement of the occupant within milliseconds of a crash. Based on similar technology, inflatable seat belts distribute the crash forces across a larger area of the body during a collision.

One of the earlier major studies that compared occupant safety when people travel with and without three-point seat belts, to analyze survival and injury rates, was conducted in Sweden in the mid-1960s. The report concluded that the seat belt offers full protection against fatal injury up to accident speeds of 60 mph and the drivers’ nonfatal injuries were reduced by 57% at lower speeds and 48% at higher speeds (Bohlin, 1967). Many global studies and meta-studies combining all earlier results have been conducted since then and they all agree that seat belts save lives. On average seat belts are estimated to prevent around 45%–50% of front seat passengers’ and drivers’ fatal injuries.

The two-point seat belt, a strap used to restrain the automobile occupant across the abdomen, was used from the mid-1950s until the three-point seat belt became the norm. Various studies show that they are not as safe as three-point seat belts and prove that in extreme conditions in automobiles it can cause severe damage to internal organs and spine and consequently fatal injuries. Five-point seat belts are commonly used in child seats. Two straps for the shoulders, two for the hips, and one between the legs are used to strap down the child to the child seat, all joined to the central buckle. Six-point seat belts are used by rally drivers and are similar to five points with the addition of a further strap between the legs.

The most prominent benefit of the seat belt is to restrain the occupant to prevent them from being thrown away from the automobile. Unbelted occupants would be thrown forward with a force up to 60 times their own weight if a collision happens while traveling at 30 mph. This is equivalent to the weight of an elephant for an average adult.

Seat-belt use rates are low, and hence the fatality rates in collisions are particularly high, in developing countries. Legislation about fittings and wearing seat belts in these countries are usually similar to developed countries; however, law enforcement varies significantly. The reasons include cultural, economic, and comfort issues and they are never simple. For public safety, widespread awareness activities, targeting all ages, is an efficient way to communicate the evidence of dangers of not wearing the seat belts.

Figure 2 Modern three-point seat belt: (A) correct use—shoulder section passing through the middle of the shoulder diagonally across the chest, lap section under the abdomen on hip bones; (B) incorrect use—shoulder section off the shoulder, lap section on the abdomen, both sections loose; (C) incorrect use—shoulder section cutting the neck lap section on the abdomen; (D) incorrect use—shoulder section under the arm, lap section on the abdomen.

The force applied on the body by seat belts during a crash can also lead to some injuries. In most cases, this is highly insignificant compared to predicted injuries if the seat belt were not worn. However, any potential injury that might be caused by the seat belt is a cause for concern for some, especially pregnant women. Many pregnant women feel the discomfort of the shoulder portion of the belt due to one of the already enlarged breasts being on its pathway. The shoulder belt and continuously riding-up lap portion of the belt also normally reside on the “bump.” Special advice, given by many transport authorities, on the correct wear of three-point seat belts during pregnancy, is based on American College of Obstetricians and Gynecologists’ advice: *The correct position for the seat belt in pregnancy is with the shoulder section passing across the shoulder, between the breasts, and around the abdomen, and the lap section passing across the hips and underneath the abdomen* (ACOG, 1999). The shoulder belt also must not cut the neck and it should not be off shoulder. The lap portion should be on the hip bones not on the thighs. Globally, correct seat-belt usage rates are very low. Research in this area suggests that a correctly positioned seat belt, without interfering with the function of the seat belt, is a very effective way of protecting the fetus and the pregnant woman. Not wearing the seat belt may have fatal consequences for both. All available patents on the seat-belt designs for pregnant women are summarized in a study by Acar and Esat (2010).

Another group of special occupants is children. In many countries it is not legal to use adult seat belts directly until they are 150 cm tall. They may be legal to use once the child is 135 cm tall in some countries; however, the shoulder section is very likely not to pass through the middle of child’s shoulder, hence to cut into the neck and not to pass across the chest. Adults in wheelchairs often use special belts to secure their wheelchairs in the vehicle and use the automobile’s three-point seat belts to secure themselves.

In future automobiles, there may be a need for seat belts with similar functionality but different shape and form that considers the safety of the occupants in a potentially different internal geometric environment and more relaxed positions and postures as in autonomous cars.

Airbags

Airbags are designed to provide a soft and strong cushion, between the occupant and hard interior surfaces of automobiles, instantaneously during collisions. Current airbags are supplemental restraint systems that work with seat belts, rather than replace them. Studies show that airbags are most effective when they are used with correctly used seat belts.

The first automobile airbags were patented in the early 1950s in Germany by Walter Linderer and in the United States by John Hetrick. They were not taken up by automobile manufacturers until at least 2 decades later; however, they inspired further research and development in the area.

The first airbags sensed the collisions through physical bumper contact (too late) and worked with compressed air (too slow). In 1968, Allen Breed invented an airbag system that detected sudden deceleration, triggering electrical ignition of sodium azide. This would in turn generate nitrogen gas, instantaneously inflating the airbag. First-generation airbags were thought to replace seat belts, especially in the United States. They were also rigid and caused secondary injuries and fatalities. In 1991, Breed co-patented an airbag that vents air as it inflates, which reduced the bags’ rigidity. The working principle of modern airbags involves sensing the collision, inflating a strong airbag from folded to fully blown state in milliseconds, then starting to deflate before the occupant hits it. This provides a soft cushion that offers protection against injuries that might otherwise occur. Currently, other explosive propellant chemicals are used rather than sodium azide, due to environmental concerns. Aluminum nitrate was also used in the past but proved to be an unsuitable propellant for airbags due to its behavior in certain atmospheric conditions such as high temperatures and humidity, which resulted in recall of large number of automobiles.

Airbags were first available for drivers and front passengers. Frontal airbags were followed by knee airbags, then side curtain airbags and side torso airbags to extend the protection to front and rear occupants from side impacts and rollovers. Rear seat passengers can also be protected by rear curtain shield and rear center airbags. Some of these airbags are dual compartment airbags providing the appropriate cushion effect according to the part of the body they contact (Fig. 3).

Figure 3 Driver airbag and side curtain airbags. Source: Photo Attribution: Aero7, licensed under the Creative Commons Attribution-Share Alike 2.5 Malaysia license, resized to fit the page.

Figure 4 Simulation of 30 km/h frontal collision with 38-week pregnant driver computational model “Expecting” wearing no seat belt (video) [\[video icon\]](#).

Modern airbag control units analyze data provided by deceleration sensors and deploy the airbags if necessary. Some smart airbags also consider details such as the weight of the occupant, impact angle, and speed to adjust airbag deployment. This may be particularly useful for a group of people with weak bodies who would get injured easily and severely.

Airbags save lives. However, the latest available report by the National Center for Statistics and Analysis (NCSA) on frontal airbag-related fatalities in 2009 reveals that in the United States, from 1990 until the end of 2008, there were total of 296 confirmed airbag-related fatalities. A significant majority, 191 (65%) of them, were children. From 1990 the numbers have gradually increased and peaked in 1997–98 then started to decrease significantly until 2008. The same report estimated the gross number of lives saved by airbags in the same period as 28,244 (NCSA, 2009).

Pregnant women have been concerned about the safety of their fetus after airbag deployment. The common advice given to them is to sit 25 cm back from the center of the steering wheel. Studies suggest that the placental abruption is less likely, and the fetus is better protected with a correctly worn three-point seat belt together with a deployed airbag compared to seat belt only, airbag only, and no restraint cases. Fig. 4 shows the simulation of a low-speed frontal crash by using “Expecting,” the computational pregnant dummy with a 38-week old fetus, in the airbag only case.

There are also exterior airbags, designed to reduce the severity of collisions, limit damage, and to save lives of both the occupants and the people that the automobile comes into contact with during a collision. Exterior automobile airbags to protect pedestrians, cyclists, occupants, and automobiles in rollover crashes and to lessen the impact of colliding automobiles have been developed or patented by car manufacturers. As in seat belts, in future automobiles, for example, in autonomous cars, there will also be a need for continued innovation.

Airbags have also been developed to be worn by and protect people who might get involved in a collision with an automobile. For example, Hövding is an airbag that works as a bicycle helmet. It was invented by two female industrial design students, Anna Haupt and Terese Alstin, in Sweden in 2005. Ordinarily, it is worn around the cyclist’s neck, but in the case of an accident, it expands and the airbag covers and protects the cyclist’s head before the impact.

Head Restraints

Head restraints are predominantly used to protect the occupant from whiplash and other neck injuries. They are sometimes mistakenly called “head rests,” presumably because it was the name when the first patent was granted to Benjamin Katz in 1923 even though the purpose was still to “stabilize the head when it was subjected to jolts and irregular movements” and to “accommodate occupants of various statures.” They are not to rest, but to restrain the movement of the head in rear-end collisions during which the occupant’s head and torso move backward relative to the seat. The seat restrains the torso; however, the head suddenly rotates backward in the sagittal plane—unless it is restrained by the head restraint—then rotates forward, resembling the movement of a whip, within 125 milliseconds.

Whiplash injury is (usually) a nonlife-threatening soft tissue injury and it is the most common and one of the most costly crash injuries. There is higher risk for women than for men. It may be experienced from sudden acceleration-deceleration force on the cervical spine due to a collision in any direction but mainly after low-speed rear impacts. Some people suffer from symptoms for a long period of time, some after a delay, and diagnosis and cure are complex due to the large number of parameters including vehicle mass, velocity (ΔV), accident type, occupant’s age, gender, stature, mass, posture, and position of the head restraint.

A head restraint is either the extension of the seat (fixed) or an addition to the top of the seat, which is usually height, tilt, and sometimes depth adjustable. Many patents were filed for fixed or adjustable head restraints especially between 1960s and 1990s. Studies show that appropriate adjustment of the head restraint can be crucial to limit whiplash injuries. However, most people are not aware about the correct positioning of their head restraints. Ideally, the back of the head should be touching

Figure 5 Backset and topset are recommended: $0 \leq BS < 7$ cm, $0 \leq TS < 6$ cm for good head restraint protection.

the head restraint and the top of the head restraint should be as high as the top of the head, but this may not be very practical. For good protection by the head restraint, BS in Fig. 5, the horizontal distance between back of the head and the head restraint (backset), should be less than 7 cm and TS, the vertical distance between top of the head and top of the head restraint, should be less than 6 cm. Unadjusted or inappropriately adjusted head restrains with $BS \geq 11$ cm or $TS \geq 10$ cm provide poor protection.

Whiplash injury represents a significant majority of personal injury claims from insurance companies. Car manufacturers have developed various mechanisms for whiplash mitigation. They can be classified into two groups. The first group is comprised of mechanisms focusing on positioning the head restraint close to the head in early stages of the rear impact. The first example of this is SAHR (SAAB Active Head Restraint) that was introduced in 1997. The system works with the occupant's weight that triggers the head restraint to move forward and upward. The NECK-PRO head restraints by Mercedes-Benz also move forward and upward but work with a sensor system which detects a rear-end collision of a predefined degree of severity. BMW's whiplash prevent system is controlled by the airbag control unit and similarly makes the head restraint move upward and forward. The second group, as in Volvo's WHIPS (Whiplash Protection System), reduces occupant acceleration by a mechanism to move the seat backward to absorb the rear-end crash energy, and upward to embrace the spine and neck, then tilts back to avoid the head rotating in the sagittal plane. Whiplash mitigating devices prevent whiplash injuries 30%–50%.

Excellent ideas to prevent whiplash injuries are developed. For example, a unique head restraint system design which adjusts its position automatically and continuously to provide the correct support for the vehicle occupant's head had been chosen as the European regional winner and the prototype was successfully demonstrated and exhibited at the 19th International Technical Conference on the Enhanced Safety of Vehicles in Washington, DC, by Loughborough University Mechanical Engineering students (LU, 2005).

Surveys reveal that most pregnant women do not adjust their head restraints and drivers in wheelchairs cannot take advantage of automobiles' head restraints.

Child Restraint Systems

Children are a very special group of occupants. They cannot directly use the seats, seat belts, and head restraints designed for adults. Hence, special seats, collectively called child restraint systems (CRSs), integrating appropriate seat belts and head restraints have been designed for their safe transport. Child Occupant protection has been included in NCAP programs.

Automobile seats for children were designed and manufactured already in the 1930s; there were multiple motivations, not including safety, as automobile safety culture was not the norm. These seats were to raise the seating level of children to enable them to see around, to limit their motions, and to be seen by the person driving the car. After the 1960s we can see that designs were evolving and making child transport safer. There are strict regulations nowadays in most countries about the manufacture and use of CRSs (Fig. 6).

Child occupant safety depends on three actions by caregivers: (1) choosing the correct CRS for the child, (2) fitting the CRS to the automobile correctly, and (3) securing the child in the CRS correctly.

For many years in the past suitable seat recommendations were based on the age and weight of the child. Lately, mainly the height is used as a measure for correct size fit. It makes sense, especially for older children, to use size rather than age. CRSs are generally recommended to be placed in rear seats. Younger children are recommended to sit in rear-facing CRSs, usually

Figure 6 Child seat from 1950s.

placed in a rear seat; however, in some countries it is legal to place them in front seats, if the passenger airbag is deactivated. Children are recommended to graduate to the next level CRS when they are too tall for their existing seats. Booster seats used to be the final seat before the adult seat; however, because boosters do not protect against side impacts, nowadays it is recommended to use CRSs with side protection. A few automobile manufacturers included integrated child seats and restraints in the rear seats.

Some portable CRSs use mechanical anchor restraints, such as ISOFIX, and some use belt installation. Comparison studies are scarce but suggest that both have advantages and disadvantages. Mechanical anchors are quicker and simpler to install correctly and hence seems to be preferred by caregivers.

Mistakes made in securing the child in the CRS also put the child in danger. For example, improperly tightened seat belts or seat belts tightened over slippery materials like some winter coats still pose hazards.

The use of CRSs has helped reduce child fatalities; however, potential errors in the three areas mentioned earlier are still a problem hindering optimum results. It is an offence not to use child seats for children in most countries, however, as always law enforcements vary.

Laminated and Tempered Safety Glass for Windows

One of the oldest effective passive safety measures which has saved many lives is the use of laminated and tempered glass in automobile windows. Regular window glass, which shatters into thin sharp pieces, was used in early automobile windshields and windows. This meant that serious injuries or fatalities after an accident were contributed to significantly by flying glass shards in addition to other consequences of the impact. Early safety glass patents were granted in 1910 in France; however, they were not used by automobile manufacturers for a long time. Laminated glass may crack under pressure and display spiderweb-like patterns but remain intact. Ford started using laminated safety glass in 1927, after refining laminated safety glass mass manufacturing (Fig. 7).

Today, all modern automobiles have laminated glass for windshields. Tempered glass is preferred for side and back windows as it is stronger than regular glass and shatters completely into tiny pebble-like dull pieces, hence eliminating injuries by broken windows during a collision and making emergency access possible.

Figure 7 Crashed laminated glass windshield.

Figure 8 Crumple zone and safety cell after a serious accident. Source: Taken from public domain. Available from: https://commons.wikimedia.org/wiki/File:Crashed_Mercedes-Benz_Coupe.jpg.

Crumple Zones and Safety Cell

The body of early automobiles were uniformly rigid, did not deform in a controlled manner, and it was believed that was necessary for automobile safety. Another most effective passive safety system, Crumple Zones and Safety Cell, was invented in 1937 and improved in 1952 by Béla Barényi, an Austrian-Hungarian engineer who later worked for Mercedes-Benz. His patent was entitled “motor vehicle with body divided into three sections.”

Crumple zones are constructed at the front and back of an automobile, and envelope a nondeformable, rigid safety cell, the occupants’ compartment. During a frontal or rear crash, crumple zones absorb and distribute the kinetic energy, deforming under control and keeping the occupants safe in the strong safety cell (**Fig. 8**). The first car with crumple zones and safety cell was manufactured in 1959 by Mercedes.

A side impact protection system introduced by Volvo in 1991 distributes the side impact force to the strengthened roof, door, and floor area rather than the B pillar alone.

Rollover protection systems, especially for convertible automobiles, protect occupants by extended roll bars behind the rear head restraints once the rollover danger is detected. The mechanism works either by a gas generator or a signal sent by the airbag unit.

Collapsible Steering Columns

Another design to protect the driver in frontal collisions is to absorb the impact energy through a collapsible steering column. It is designed to prevent injuries the steering column and steering wheel can cause. In principle, a non-collapsible steering column is one long shaft connected to the gearbox. Many patents exist on collapsing mechanisms, most working like a telescope, starting to operate when the force from front-end impact is above the threshold. One of the early patents belongs to crumple zone and safety cage inventor Béla Barényi. The collapsible steering column is a commonly used passive safety measure since 1967.

Other Effective Safety Measures

Most of the current passive safety developments are based on hard work of determined researchers and advancing technology. They form parts of the “safety competition” between car manufacturers. However, in early days the introduction of simple passive safety measures made significant changes in people’s safety. Avoiding sharp edges, and protruding features, using padded dashboards and changing rear-view mirror location in automobiles can be counted among these developments. Front opening (rear-hinged) doors were quite common in the old days and they were nicknamed “suicide doors” because of potential risks of opening doors at speed. Only a few rear-hinged door (with modern locks) automobiles are available currently. There is also the child safety lock, a simple mechanism designed to avoid children (or any rear seat passenger) opening the automobile doors without authorization. When the child safety lock is activated the door can only be opened from outside. It has been a common feature in most family cars since the 1980s.

Acknowledgments

The author would like to thank EPSRC (Engineering and Physical Research Council, United Kingdom) that has funded a number of her research projects on automobile safety and Thatcham Research for its collaboration in the projects. The author also thanks people who modeled in the photographs, the Editor for his useful comments, and Baris and Baran for their constructive suggestions on the earlier draft of the article.

Biography

B. Serpil Acar is the Professor of Design for Injury Prevention at Design School, Loughborough University, United Kingdom. She received BS and MS degrees in Mathematics from the Middle East Technical University, Ankara, Turkey. After completing her PhD in the United Kingdom, she worked in close collaboration with engineering departments as well as automotive industry and clinical and academic members of the Medical Schools in the United Kingdom. Her current research interests include occupant safety, engineering design for women, and modeling the human spine. She is the principal investigator of many major Engineering and Physical Sciences Research Council funded projects investigating occupant safety. She is the winner of the 2012 Enterprise award with her invention SeatBeltPlus, a device for pregnant occupant safety.

Introduction

A pedestrian is a person traveling on foot from one location to another. So are people walking or jogging for recreation. People using wheelchairs and people on skateboards or similar devices are in many jurisdictions also considered to be pedestrians. Walking as a means of transportation has the potential to increase physical activity for children on a daily basis, if chosen as the main mode for the daily commute to and from school, leisure activities, or the like. Furthermore, walking provides children with the possibility for independent mobility, bonding with peers while walking, as well as improving their individual spatial and navigational skills. Thus, walking can potentially improve the quality of daily life for children due to related improvements in their physical, social, and mental health. However, despite potential individual and societal benefits, walking is also associated with a high risk of road crash involvement and related injury. This chapter provides an overview of key aspects regarding child pedestrian safety, including crash involvement, characteristic and consequences, age-related capacities for safe behavior and selected countermeasures. In this article, we define a child pedestrian to be a pedestrian below the age of 18.

Crash Involvement

Worldwide, pedestrians constitute around 22% of all police-reported road fatalities. Male pedestrians are overrepresented among all age groups and that is the case for child pedestrians as well. Furthermore, pedestrian crashes is the largest category of road traffic crashes involving children. The percentage of children in pedestrian crashes differs between countries, especially between high- and low-income countries. In high-income countries, child pedestrians constitute 5–10% of children involved in road traffic crashes, whereas in middle- and low-income countries, child pedestrians are injured or killed in 30–40% of road traffic crashes (WHO, 2008a). In Africa and Asia, where people often walk along the side of the road, the number of injured child pedestrians is particularly high. In recent years, the number of child pedestrian injuries has been reduced significantly in many high-income countries. However, despite indications of a positive development, the prevention of child pedestrian injuries remains a worldwide challenge, especially for children of the age group 5–14. In Europe, 48% of road deaths among children, involve a pedestrian. Socioeconomic factors strongly influence the risk of being killed as a child pedestrian. The risk of being killed, as a child pedestrian is four times higher for children from the lowest compared to the highest socioeconomic classes, and 20 times higher for children with unemployed parents.

Crash Recording

Several factors challenge access to knowledge about child pedestrian crashes and related injuries. First, only an injury related to an incident in which both a child pedestrian, and a vehicle (cycle, moped, motorcycle, car, etc.) are involved, is considered a road traffic crash. Consequently, injuries related to incidents involving only one child pedestrian or several pedestrians, for example stumbling in the street, slipping on an icy surface, stepping into a hole in the pavement, or the like, are not registered as road traffic crashes or road traffic crash-related injuries. This is also the case for incidents where the slipping, stumbling etc. was caused by crash avoidance maneuvers, such as trying to avoid a collision with an approaching vehicle. When considering crash involvement among child pedestrians, it is therefore important to be aware that road traffic crash only includes incidents that meet certain criteria. Second, only pedestrian crashes recorded by the police are included in the official road traffic crash statistics. Underreporting of road traffic crashes

is high, especially for vulnerable road users and less severe crashes. The degree of this underreporting differs across different countries, but in most countries, less than half of the road traffic crashes, that involve a pedestrian, are recorded by the police. In some countries, the degree of underreporting is even higher. Furthermore, recent studies indicate that the quality of the information about pedestrian road traffic crashes, recorded by the police, is sometimes low, and therefore, somewhat unreliable. Consequently, it is important to be aware that the available information about child pedestrian crashes is limited and biased in a number of ways.

Crash characteristics

Characteristics of child pedestrian crashes generally mirror their activities and mobility patterns, as well as the capacity and skills for safe road user behavior of children at different ages. Consequently, characteristics of child pedestrian crashes, involving younger children, differ from crashes involving older children, in regard to aspects such as location, road environment, and behavioral contribution to the occurrence of the crash (Petch and Henson, 2000). Regarding crash location, the majority of crashes, involving young child pedestrians, occur close to where they live. For instance, in a study from Great Britain, it was found that 70% of crashes involving a child pedestrian below the age of 5, occurred within 1 km from the child's residence. And out of these, approximately one-third of the crashes occurred right in front of their home. As the age of the child increases, the distance between the crash location and the residence of the child increases too, thereby mirroring the age-related increase in the radius of independent mobility. For older child pedestrians, the majority of crashes occur during the daily commute to/from school and leisure activities away from home. For younger child pedestrians, the crashes mostly occur to/from kindergarten or during play, either just in front of their home or very close-by. Thus, as the allowed radius of independent mobility increases with age, so does the distance between the crash location and the residence of the child.

In regard to characteristics of the road environment at child pedestrian crash locations, the prevalence of child pedestrian crashes is higher on locations with certain characteristics. In general, crash occurrence is higher on locations, where the area used by the child for walking or playing, is not separated from motor vehicles and other road users. Thus, the prevalence of child pedestrian crashes is higher on locations with limited access to playgrounds, gardens, and other green areas. At locations where such facilities are missing, children are left to play on the sidewalk or in the street, thereby increasing the risk of being hit by other road users. The number of parked vehicles is also associated with child pedestrian crash occurrence, and the crash rate is comparably high on locations with a high level of on-street parking and limited off-street parking facilities. In addition, the literature indicates a comparably high number of child pedestrian crashes on locations with long, straight, and high-speed roads, especially if they have limited pedestrian facilities and a high level of through traffic. Studies suggest that more than 90% of child pedestrian crashes occur on not dead ends streets. However, on average, the average collision speed is lower for child pedestrian crashes, compared to the average collision speed in crashes with adult or elderly pedestrians. In a retrospective Austrian survey (Mayr et al., 2003) among parents of child pedestrians ≤ 16 years old injured in a road traffic crash, it was found that 38% of the crashes happened at locations with zebra-crossings with, or without, traffic signals. Neither zebra-crossings nor signals were present at the crash location of 58% of the crashes. In addition, 37% of the pedestrians were alone at the time of the crash, parents or other adults accompanied 32%, and 24% were with other children. The majority of crashes happened during the daytime, particularly between noon and 5 p.m., and the majority of crashes happened in sunny and dry weather conditions. In general, the crash risk of child pedestrians increases with vehicle speed and traffic volume, especially on locations where the road design does not support separation of the child and the motor vehicles.

Crash Contribution

Due to the complex nature of crash occurrence, care should be taken when assessing crash causes. However, looking at the circumstances connected to child pedestrian crashes, studies indicate that the child's contribution to the crash occurrence differs depending on the age of the child. Like differences in crash location and road environment, these differences mirror the age-related differences in activities at the time of the crash. When 1–2-year-old children are involved in a road traffic crash, it is more likely to occur in a situation in which a car is backing up on a driveway or similar, while the child is playing. The child contributes to the crash occurrence merely by being present, and unfortunate behavior of the other road user—for the back-up crash, in combination with the lack of back-up cameras connected to audible warning signals—appears to be the main contributing factor to the occurrence of these crashes. From the age of around three, crash involved child pedestrians contribute more actively (although not intentionally) to the crash occurrence. For 3–9-year-old children, crashes often occur in situations in which the child plays in the street, runs out into the street from the sidewalk, or from between parked cars, or tries to cross the street at an unsafe distance from oncoming traffic. Thus, although the other road user may also contribute to the occurrence of the crash by speeding, being inattentive, being impaired by alcohol etc., the behavior of the child pedestrian also contributes to the occurrence of such crashes. This is also the case for child pedestrians aged 10–14; however, at this age the contribution of the child pedestrian also includes violations, such as not obeying a traffic signal.

Crash Consequences

Child pedestrians are vulnerable to physical injury in case of a crash, due to lack of protection from a vehicle (e.g., airbags) or personal safety equipment (e.g., helmet, protective clothing). The difference in mass, between the pedestrian and the other party, also contributes to the vulnerability. Consequently, the degree of severe injury is generally higher for pedestrian crashes, compared to

crashes among other road users, and as such, pedestrians are the most vulnerable road user group. A German study (Niebuhr et al., 2016), analyzing 1422 pedestrian–car collisions with injury, found that the severity distribution for child pedestrian crashes was different from the severity distribution for crashes involving pedestrians in other age groups. More specifically, below collision speeds of approximately 69 km/h, the risk of serious injury was lower for children below the age of 15 than for other age groups. At collision speeds above 69 km/h, the risk of being seriously injured as a child pedestrian was higher, than the risk for adult pedestrians. These results indicate that compared to pedestrians in other age groups, the risk of being injured for child pedestrians was lower at lower collision speeds but higher at higher collision speeds. Differences in force impulses, and the relation between the upper leading edge of the vehicle and the pedestrian's center of gravity may explain this. When hit by a vehicle, children are typically pushed out in front of the car, whereas adult pedestrians rotate over the vehicle. In an Austrian study, it was found that 27% of the child pedestrians injured in a road traffic crash suffered physical consequences, primarily troublesome scars, but recurring headache and pain in the lower extremities were also among the more frequently reported physical sequels. Less frequent consequences included pain in lower and upper extremities, motion restriction, tooth damage, impairment of cerebral function, and back pain. The chance of long-term physical consequences was reduced if the vehicle was braking at the time of the crash, but increased with vehicle speed and number of vehicle parts, by which the child was struck.

Traditionally, the focus is on the severity degree of the injury in terms of physical person injury. However, child pedestrian crash involvement may also have psychological consequences, such as PTSD for the child pedestrian and/or for the child's family. In the Austrian study mentioned above, 24% of the child pedestrians, injured in a road traffic crash, suffered from long-term post-traumatic behavioral and psychological disturbances, with fear of traffic being the most prominent, followed by being generally more nervous, and behaving more carefully. Other disturbances include aspects such as generally being more fearful, psychometric retardation, lack of concentration, and sleep-related disturbances. Also, 11% of families of the crash involved child pedestrians suffered from post-traumatic psychological disturbances. Fear of losing a child was the most prominent, but being more careful also occurred relatively frequently. Other aspects include feelings of emptiness, being stressed by the child's behavior, and being more contemplative. A French study on post-traumatic stress symptoms in school-aged children, injured in a road traffic crash, found, that peritraumatic distress was a robust predictor of acute PTSD symptoms, 5 weeks after the crash. Children suffering from comprised mental retardation, lifetime psychotic disorder, and life-threatening conditions were not included in the study. Of the included children, 34% were pedestrians at the time of the injury.

Cognitive Capacity and Skills

The ability to understand and predict the behavior of other road users, and to relevantly adjust one's own behavior accordingly, is a key element in child pedestrian safety. However, for child pedestrians this ability is challenged, due to age-related limitations in cognitive capacity and skills, as well as perceptual and motor abilities. While recent research indicates that human cognitive development continues until the mid-20s, some research also indicates that by the age of 10–12, children's cognitive capacity allows them to handle most traffic situations on their own, except complex ones. In short, the cognitive capacities and skills needed for safe child pedestrian behavior comprise of attention, perception, information processing, and decision-making, all of which develop with age (e.g., Schwebel et al., 2012). Small children focus spontaneously on their immediate surroundings, have difficulties controlling their attention, and even 7–8-year-old children get easily distracted in traffic. Consequently, their ability to identify relevant areas of attention, and to intentionally focus on approaching traffic, is limited. Visual and auditive information is of particular importance to child pedestrians, in order to locate other road users and anticipate traffic development. Research suggests that visual acuity is lower in children at the age of 5 compared to 8–11 year olds, as well as compared to adults. Limitations in visual acuity may, therefore, cause young children to miss critical information about safety. In regard to auditive information, the ability to locate an object develops early, whereas the ability to interpret the auditive information improves with age. However, as child pedestrians must collect and process dynamic visual information about the road environment to make safe behavioral decisions, the fact that the span of the working memory develops and improves with age is also of key importance for the cognitive processing of visual and auditive information. Due to these developmental challenges, the ability to collect and apply relevant sensory input is more challenging for younger, compared to older, child pedestrians. However, the relative contribution of limitations, related to collecting and interpreting the information, remains unclear. In regard to information processing, the child pedestrian is also challenged by age-related limitations in the ability to process and integrate multiple sources of information within a short period of time. Furthermore, the ability to predict future development in the traffic situation, and, for instance, anticipate upcoming slots for safe road crossing, is poor. Consequently, timely strategic behavioral decisions are difficult. Smaller children need more time to collect and process critical safety information than older children and adults do, and by the time the small child is ready to cross the street, it may be too late to do it safely. However, it is not clear if the process is also delayed by the process of translating the decision to cross, into actual behavior and movement of the body.

Countermeasures

Safety for child pedestrians can be improved from two directions: creating a safe environment and increasing child pedestrian safety skills. Creating a safe environment includes measures such as separating child pedestrians and motor vehicles, and reducing the speed of the motor vehicles. Examples aimed at the motor vehicles include speed bumps, moving the stop line further away from intersections and pedestrian crossings, as well as vehicle-based safety improvements, such as pedestrian friendly fronts or pedestrian

detection systems. Measures directed at the child pedestrian include measures such as overpasses and underpasses, which allow children to cross a road while spatially separated from the motor vehicles, but also other measures offering clear guidance while respecting the cognitive capacity of the child, regarding where and when to walk or play and to identify safe road crossing times and locations. However, safety measures only serve to improve child pedestrian safety when used as intended. Thus, careful consideration of the behavior, needs, and limitations of child pedestrians should be taken when implementing such measures. For example, if the location of an underpass is inconvenient, the child pedestrian is less likely to use it, and if the child perceives it as unsafe due to design issues, poor lighting, lack of overview, or other subjective perceptions, he/she may choose to cross the street not using the underpass, thereby unintentionally increasing the risk of crash involvement. In addition, signalized intersections, zebra crossings, and other measures, that provide clear guidance to the child pedestrian as where to walk or play, may provide the child with a false sense of safety, and consequently, lead it to not pay sufficient attention to approaching traffic. Thus, measures to improve child pedestrian safety should take the needs, perceptions, motivations, etc. of child pedestrians into account. In addition to designing the road environment in ways that support child pedestrian safety, child pedestrian safety can be enhanced by the safest possible usage of the existing environment. This can be done by identification of the safest routes to school, leisure activities, etc. along with parental encouragement to choose these routes. In addition, child pedestrians may benefit from the use of conspicuity aids and light-colored and retroreflective clothing, dangle tags, armbands and strips on school bags, etc.

Even though the child pedestrian's ability to engage in safe road-user behavior depends on their age-related cognitive capacity, it is possible to improve their safety skills by training. Research indicates that lack of skills and strategies, for optimal use of the actual cognitive capacity of the child, enforce the age-related limitations. Therefore, training programs targeted at improving safety skills among child pedestrians, should aim at improving the needed strategic skills, rather than focusing on knowledge or rule-based learning (Thomson et al., 2005). Thus, instead of only practicing the actual crossing of the road, training programs should aim to develop the needed critical safety skills, such as estimating time-distance, the relation between available time and needed time, and skills in terms of anticipation and planning ahead. In addition, research suggests that the presence of peers is associated with increased risk of injury for child pedestrians, and that perceptions of social norms among peers influence child pedestrian behavior. Thus, measures aimed at supporting safety enhancing social norms among peers and changing child pedestrians' perceptions of the behavioral norms of their peers, are relevant. Finally, it is relevant to encourage and prepare parents accompanying child pedestrians to use such moments, as an opportunity to teach their child about safe road user behavior, while taking the age of their child into account.

Conclusion

The risk of crash involvement and serious injury is high for child pedestrians particularly in low-income countries. Crash characteristics and circumstances change with the age of the child and mirror age-related differences in activities and mobility patterns. Factors contributing to crash involvement and injury include lack of protection from vehicle or personal safety equipment, unsafe road environments and age-related limitations in cognitive capacity and skills. Key preventive measures include spatial separation of child pedestrians and motor vehicles, reducing speeds to no more than 20 km/h of motor vehicles where separation cannot be achieved, and training focusing on safety critical strategic skills. However, measures aimed at social norms and involvement of parents are also relevant.

Biography

Mette Møller, PhD, is a Transport Psychologist. Mette Møller's main research field is road user behavior, crash analysis, crash prevention, and road safety.

Glossary

jaywalk The act of illegally crossing a road, either at junctions or midblock, into the traffic flow.

motorcycles Also known as motorbikes. It is a form of two-wheeler vehicle, typically using gasoline engines. It may be used to carry people as well as goods.

pathway A dedicated, paved walkway or sidewalk especially provided to separate pedestrians from motorized traffic.

pedestrian Any person, regardless of age and physical conditions, who walks either for the entire journey or part thereof.

personal mobility devices (PMD) A form of transportation that includes hoverboards, kick-scooters, and e-scooters.

Overview of Pedestrian Safety

Pedestrians are people who walk to achieve some travel goals, regardless of age and personal physical conditions. These travel goals may include, among others, commuting to school or work, shopping, recreational, sightseeing, or socializing. Walking can either be for the entire journey or part thereof. The activity may take place on a paved sidewalk or pathway on the ground, overhead bridge, underground tunnel, along a trail, or at the edge of a street or road lacking adjacent walking facilities. When pedestrians have to walk in the road or on the roadside, competing for the same road space as motorized vehicles, safety is obviously a concern. Pedestrians also include those who run, jog, sit, or lie either on the pathway or alongside a roadway. For the physically challenged people, walking may be assisted by crutches, canes, walkers, or wheelchair. Sometimes, where space is limited, or funds are not appropriated in sufficient amounts, other groups of users may share the space with pedestrians. These other groups of users include cyclists and users of personal mobility devices (PMD), such as skateboards, hoverboards, or e-scooters.

Due to different profiles of pedestrians, the mixture of users on pathways, and the need to safely share the roadway with other road users (**Photo 1**), pedestrian safety is increasingly becoming a complex issue yet one that must be tackled to ensure safe and comfortable passages to those who choose to walk. The issue of pedestrian safety may become more critical in certain cities where the city legislation allows the citizens to take legal remedy from the local government due to negligence of providing and ensuring safety along the pathway.

The Need for Pedestrian Safety

Every pedestrian has specific desires, needs, and physical limitations. For example, a disabled person in a wheelchair requires a ramp to access the pathway, whereas a senior citizen requires a longer green time to safely cross a junction due to lower walking speed.

Photo 1 Pedestrians, bicycle, and motor vehicles coexist safely in Utrecht, the Netherlands.

Risk profiles of pedestrians are different at different places and times. The risks of accidents between pedestrians and motorized vehicles are higher at a busy intersection than, for example, inside an airport terminal where only electric buggies are present. Subsequently, the risk of crossing a street may multiply many folds at night or during adverse weather. Failure to address the risk exposure of the pedestrians may consequently lead to discomfort, inconveniences, bodily injuries, or even death. Hence, it is important for city officials to plan, design, and construct pathways that guarantee not only comfort and convenience, but also safety. And, equally important, a safe walking environment will promote, motivate, and convince residents to participate actively in walking as an alternative to using private vehicles.

Pedestrian Safety Versus Pedestrian Security

The term pedestrian safety should not be confused with pedestrian security. Though both safety and security have adverse consequences to the pedestrians, they are not synonymous and are not interchangeable.

Pedestrian safety refers to situations when there are potential risks of personal injuries due to civil activities (e.g., driving or using mobile phone while walking) or due to hazards from physical obstructions and natural environments (**Photo 2**).

Pedestrian security, on the other hand, refers to risks of personal injuries due to criminal activities. Some examples of incidences leading to security risk include snatch theft, street crime, kidnapping, and terrorism as in the case when motor vehicles are used as weapons of destruction to slam into pedestrians and cyclists. Hence, protruding tree roots on the pathway is a hazard to pedestrian safety, but mugging is a risk to pedestrian security.

The remedies to mitigate both risks may be similar or different. Installing adequate and strategically placed lighting along the pathway may address both safety and security risks. However, installing a network of closed-circuit television cameras may only address security issues, but not necessarily mitigate safety risks.

Photo 2 Safety is about managing movement conflicts and physical obstructions that are risks to pedestrian safety.

Photo 3 Improper placement of fire hydrant along pathway.

Causes of Accidents

Walking, just like driving or any other form of transportation, has its associated safety risks. For pedestrians, the safety risks are extremely high and serious as pedestrians are the most vulnerable among all road users due to the absence of any form of physical protection. Understanding and profiling these risks and causes of accidents to pedestrians are imperative to city managers. Knowledge of these risk profiles helps in the formulation of strategies, action plans, and design guides to improving walkability and safety in a city. Generally, there are four factors that contribute to elevated risks to pedestrian safety—physical obstructions factors, vehicular factors, design factors, and human factors.

As pedestrians walk, they interact directly with the built and the natural environment surrounding them throughout their journey. The built environment such as sidewalks and street pavements, street furniture and buildings, and the natural environment such as trees and shrubs increase the esthetic value of the pathway as well as provide positive and enjoyable travel experiences to the pedestrians. Yet, in some cases, the built environment and the natural environment can become hazardous and turn into safety risks when they create physical obstructions. Trees become hazardous when low-hanging branches are not trimmed or when roots protruding into the sidewalk create an uneven travel surface. As for sidewalks and walking paths, they ought to be paved rather than gravel and are typically made of concrete (Stoker et al., 2015), asphalt, bricks, or tiles. If not well maintained, they may over time become cracked, broken, or loose, thus impeding smooth travel. In these circumstances, pedestrians may become injured when they accidentally trip over protruding tree roots or broken tiles. Even if accidents are avoided, pedestrians may still have to circumnavigate around the protruding tree roots, and surface bumps or holes resulting in a less than desirable walking experience. Similarly, street furniture such as lampposts or fire hydrants may be improperly placed on the walking path of the pedestrians creating man-made physical obstructions (Photo 3). For the visually impaired individuals, these physical obstructions are major hazard to their safety as well as interfere with their navigation along the pathway.

Another form of physical obstructions is commonly found around construction sites. Due to lack of guidance or enforcement by the local government and occupational safety agency, building contractors or their agents may encroach into the walkway resulting in partial or full closure of the pathway. When this happens, pedestrians are forced to use alternative paths to continue their journey by encroaching onto the roadway. As the pedestrians enter the roadway, they will directly compete for the same road space as motorized vehicles use. These conflicts between pedestrians and motorized traffic are accidents in the making. Additionally, construction sites are also a source of industrial debris that may endanger the safety of the pedestrians. Without proper roofing and scaffolding, the industrial debris may hit the pedestrians causing grievous injuries.

Motor vehicles, either moving or static, are perennial sources of hazards to pedestrians and they are ideally not meant to ever be in the same physical space. Yet, there are numerous times when conflicts happened leading to accidents that can cause serious injuries and even be fatal. Protecting pedestrian safety from the hazards of motorized vehicles means at a minimum to effectively providing an unobstructed visual line of sight for both the pedestrians and the drivers. This contributes to separating the pedestrians from the motorized traffic as well as controlling the flow of vehicles and pedestrians. One source of obstruction of the visual line of sight is parked or stopped vehicles. Parked or stopped vehicles, especially trucks, buses, trams, and other big vehicles, may prevent pedestrians from having a good, clear view of oncoming traffic. This is especially critical at an unsignalized junction lacking crosswalks where the pedestrians have to rely on visual sight to safely enter the roadway and cross the street. Similarly, drivers also need to be able to detect the presence of pedestrians attempting to cross at an intersection to be able to stop their vehicles in time and at a safe distance from the crossing pedestrians. As for moving vehicles, they may skid and encroach into the pathway possibly crashing into the pedestrians. In cities with temperate climate, skidding vehicles are a fairly common phenomenon during the winter season due to slippery road surfaces and vehicles may slide sideways onto sidewalks as well. For such locations, protecting pedestrians from skidding vehicles poses a greater challenge requiring specific measures including promoting on-street parking as a form of barrier to the pedestrians.

In other situations, speeding vehicles and vehicles driven by intoxicated drivers encroaching into pedestrian pathways are even harder to control as their occurrences are hard to predict, though preventable. Yet, there have been many cases where irresponsible drivers have killed pedestrians. And, in many jurisdictions, vehicles are allowed to travel at speeds that are not compatible with

Photo 4 Motorcycle using pedestrian pathway as alternative route.

pedestrian movements. When top speeds are kept below 30 km/h, and preferably below 20 km/h, pedestrians are typically able to avoid getting hit by vehicles. However, parallel movement of vehicles in multiple lanes can pose a risk to pedestrians even at relatively low speeds since vehicles obstruct pedestrians from each other as discussed earlier. So, the possibility of these risks on pedestrian safety should not be discounted or accepted.

Another form of hazards posed by motorized vehicles is when vehicles illegally enter the pathway and use it as an alternative route (**Photo 4**). Motorcycles (e.g., scooters and mopeds), due to their small size, may find the pathways tempting due to lack or absence of motorized traffic there, whereas the travel lanes are congested. For these motorcyclists, using the pathway as an alternative route then can save significant traveling time especially along highly congested roads. Their presence on the walkways, hence, poses serious danger to the pedestrians. Where demand of parking spaces exceed supply, some cities find that motor vehicle owners use and treat the pedestrian pathway as an additional source of supply of parking spaces, albeit illegally (**Photo 5**). In Asian cities such as Hanoi, Vietnam, and Pune, India, where motorcycles (e.g., scooters and mopeds) are a major form of transportation, the problem of encroachment into pedestrian pathways is a major issue for city officials. When moving, these motorcycles may hit pedestrians and when parked they present a physical obstruction to pedestrian mobility.

Poor land-use planning and design is another risk factor to pedestrian safety. The absence of pedestrian pathways in residential neighborhood is an example of bad design. Over the course of designing residential neighborhood layouts, town planners may put form and esthetic over function. Spaces are generously provided for landscaping, yet nothing is allocated for the provision of pedestrian pathways. This will ultimately create a highly car-dependent community, as it is too dangerous to walk around in the neighborhood. Children will then not walk to school but be taken by their parents in private vehicles. Even a short trip to the neighborhood shops will be done using private vehicles. As private vehicles become a life necessity, every adult family member will own a private vehicle, or two. With no adequate space to park their vehicles within the residential compound, the vehicles will overflow onto the streets thus escalating the risk of walking.

Similarly, the placement of land uses with high walking demand potentials, for example, schools and commercial complexes, along a busy road or next to a busy intersection, not only creates access management nightmares but also induces safety risks to

Photo 5 Parked motorcycles on pathway obstructing pedestrian movement.

pedestrians. Pedestrians who consistently are exposed to high traffic volumes make crossing the road, either at a junction or midblock, a risky and time-consuming affair, especially in jurisdictions where automobile drivers do not have the obligation to yield to pedestrians. When pedestrians assume that it will take significant amounts of time to wait for traffic to ease before attempting to cross, they become increasingly willing to take high risks and attempt crossing in short time gaps and in unguided ways—which is in fact a gamble with safety and their life. Lastly, poor design may also contribute to disconnected pedestrian networks.

Lastly, the behavior of pedestrians themselves may invite safety risks. A new phenomenon called the “zombie” is when a pedestrian is too engaged with their mobile devices (e.g., reading, texting, talking, playing games, etc.) while walking. These “zombies” are oblivious of their surroundings including potential hazards and movement conflicts. The “zombies” may bump into other pedestrians, trip over protruding tree roots, or fall into uncovered stormwater drains. Another self-destructive pedestrian behavior is jaywalking when pedestrians consciously walk into streets where motorized traffic is given the legal right-of-way. In most jurisdictions, pedestrians do not have the right-of-way in-between intersections (midblock) unless there is a marked crosswalk. In some jurisdictions, pedestrians do not have the right-of-way at intersections either unless there is a marked crosswalk. And even when the pedestrians clearly have the right-of-way, drivers may intentionally or unintentionally fail to give priority to pedestrians. So, jaywalkers as well as legally crossing pedestrians often risk their lives in return for their own and motorists’ convenience and time savings.

Road User Hierarchy

There are strategies and actions that can be implemented to mitigate the risks to pedestrian safety. These strategies and actions are normally included in citywide pedestrian master plans or pedestrian facilities design guidance. The master plan and design guidance are published after a series of detailed engineering and land-use studies: demography, travel behavior and mobility analyses, and community consultations to account for specific local issues, cultures, as well as planning and urban design philosophies. In preparing the master plan or design guidance, some cities adopt well-known principles such as the universal design, complete street, and safe city principles.

Regardless of the design principles used, the basic underlying concept is the concept of road user hierarchy. This concept establishes the priority level of every road user. In this hierarchy (Fig. 1), pedestrians typically should be given the highest priority, followed by cyclists, transit vehicles (e.g., buses and trams), and motorcycles. Private cars and trucks/lorries should be at the lowest end of the hierarchy. Adopting this hierarchy requires that city officials give guarantees, in their design, planning philosophies, and development processes, that pedestrians are given the top priority to the roadway use and all other road users must give priority to the convenience, comfort, and safety of pedestrians.

Protection Zone for Pedestrian

As the most vulnerable group of all road users, pedestrians must be protected from all potential hazards. To provide for this protection, a zone surrounding an individual pedestrian must be established (Fig. 2). The desired dimension of this protective zone is 2.0 m wide by 3.0 m high. Where space is limited, the width can be reduced to a minimum of 1.5 m.

Figure 1 Hierarchy of road users.

Figure 2 Pedestrian protection zone.

Within this protective zone, there should not be any physical element (e.g., tree branches, signs, street furniture, parked bicycles, etc.) that would present a hazard obstructing safe passage of pedestrians. The establishment of this protective zone will significantly reduce the risk to pedestrian safety.

Designing for Pedestrian Safety

The main cause of accidents involving pedestrians is conflict between pedestrians and motorized vehicles. Through effective segregation, or effective integration—such as the use of shared space—conflicts between these two groups are preventable (Huybers et al., 2004). Segregation can be achieved through spatial separation acting as a buffer between pedestrians and motorized vehicles (Fig. 3), creating the spatial separator effectively dividing the right-of-way into three zones—the pedestrian zone, the buffer zone, and the traffic zone.

The effectiveness of the buffer zone as spatial separator can be enhanced through planting of trees acting as a natural physical barrier. Trees also bring the added benefits of natural shades as well as increasing the esthetics of the surrounding areas (Photo 6). However, the choice of trees must be properly selected as protruding tree roots are potential hazards to pedestrian safety. Other than as a place to plant trees, the buffer zone can also be a convenient place to install street furniture, for example, benches, fire hydrant, wayfinding signage, or streetlights, as well as a place to install public utilities.

Segregation can also be achieved through having physical barriers, for example, fences or curbs (Fig. 4). Similar to spatial separation, the effectiveness of the physical barrier can be enhanced by combining various tools, for example, combining curbs and fences. Fences, especially non-climbable ones, are effective measure to prevent, or at least discourage, jaywalking.

For the best solution, combining both spatial and physical separation is the most effective measure of separating the pedestrians from the motorized traffic (Fig. 5).

The minimum width for the pedestrian zone (i.e., pedestrian pathway) is 1.5 m. This minimum width is sufficient for two individuals to walk side by side and for easy maneuverability of wheelchairs for people with physical disabilities. At locations where the pedestrian volume is high, this minimum width is inadequate and should be increased to a minimum of 2.0 m. However, if the

Figure 3 Buffer zone as spatial separator.

Photo 6 Combination of landscape as spatial separator and shades providing pedestrian with comfort and safety.

Figure 4 Fence and curb as physical separator.

Figure 5 Combining spatial and physical separators.

pathway is to be shared with bicycles or PMD (e.g., e-scooter), then a minimum width of 2.5 m is desirable to ensure safe passing and to avoid unnecessary conflict on the pathway. Where a barrier curb is provided, the desirable height should not be less than 15 cm. As for the fence, a minimum height of 1.0 m is required to effectively discourage climbing over the fence. Some fences, however, have already incorporated non-climbing feature into its design which is preferable on streets where the probability of jaywalking is high, and it has been determined that vehicles should be given uninterrupted passage. To reduce the effect of hardscape of the fence, planting of shrubs is recommended (Photo 7).

Photo 7 Effective use landscape to soften the effect of fence.

Traffic Devices for Pedestrian Safety

Another major source of safety risk for pedestrians is where they cross at nongrade separated intersections where conflicts between pedestrians and motorized vehicles are imminent (Miranda-Moreno et al., 2011). Here, spatial and physical separations discussed earlier are not possible. Instead, separation can be achieved through effectively regulating flows of pedestrians and motorized traffic. Controlling and regulating pedestrian and traffic flows at cross-junctions can be achieved through using traffic devices such as traffic signals and signs. For the drivers, both signals and signs provide them with visual cue of impending conflicts with pedestrians as well as instructions on their vehicles' movements. Similarly, signals provide instructions to the pedestrians on when it is reasonably safe to enter the roadway to cross to the other side, especially if speeds are kept low—not above 30 km/h—so that drivers are not encouraged to run red lights near the change intervals. Combined with alarm beacons, pedestrian crossing signals provide the visually impaired audible cue to cross the streets.

Traffic calming devices can also be an effective tool to enhance pedestrian safety. These devices, for example, speed breaker and speed humps, force drivers to slow their vehicles when approaching pedestrian crossings. The speed table, a form of speed hump with a flat top surface, may double as crossing path for pedestrians and, if the ramp is not too short and not too long, and its height is at least 10 cm, they reduce speed effectively. In some locations, chokers and road diets (i.e., narrowing of streets) may be combined with speed tables not only to further enforce lower traveling speeds, but also to provide a convenient and safe crossing facility for the pedestrian. However, the suitability of each potential traffic calming measures must be extensively studied before implementation so as not to hinder smooth passage of emergency service vehicles such as ambulances and fire engines.

Issues and Potential Solutions

Ensuring safety of pedestrians is a conscious, disciplined effort and it requires deep understanding of the built environment, demography, and travel behavior (Asadi-Shekari et al., 2015; Chimba et al., 2014). Only then careful design and planning of pedestrian facilities that incorporated safety can be performed. This is a huge challenge where providing pedestrian walkways, and subsequently pedestrian safety, is not considered a priority or even somewhat important by decision-makers.

Generally, the lack of focus on pedestrian convenience and safety is more prevalent in developing and underdeveloped countries where cities are still struggling with motorization. Often, priority and resource allocation are assigned more to alleviating motor-vehicle congestion and improving travel time for motorists than providing comfortable and safe pedestrian pathways. Some cities in Africa and Central Asia, for example, are notorious for their unsafe walking environments as dedicated pathways for pedestrians are absent from most part of the city. In these cities, walking means being in the same space, and competing for the same space, with motorized vehicles. Here, people walk, not because of choice, but rather because they have to as there are limited economically viable mobility alternatives. On the contrary, in developed countries, most of their cities have already given priority to pedestrians to encourage active mobility as a means to discourage and limit motorization. Cities such as Berlin, Copenhagen, Boston, Melbourne, Paris, Kyoto, and Singapore are notable for their walkability. Here, locals and tourists walk not only because it is convenient and comfortable, but also because they feel safe doing so. Hence, the first hurdle to protecting the safety of pedestrians is to provide a dedicated space that separates the pedestrians from the motorized traffic. The next step is to narrow down the part of the streets that is open to motorized traffic and widen sidewalks in connection with lowering speed limits like Berlin has done where much of the downtown now has a 10 km/h speed limit.

A solution to guarantee the provision of pedestrian pathways is by making it mandatory for any property/land-use developer to include pedestrian pathway in any newly proposed land-use development. However, this mandatory requirement must be incorporated as a rule for development submission, not merely as a set of best practices or even standards. In other words, failure to

include provision of pedestrian pathway in the development submission will automatically render the submission noncompliant and be rejected. This rule, however, is easily incorporated into existing development law if both city officials and property developers understand the importance of providing proper facilities to support walking and sustainable development. However, in a profit-first and profit-maximization society, property developers might resent such development law requiring mandatory provision of pedestrian pathway and facilities. The developers will view such pedestrian-centric laws as costly and effectively reduce their profit margin. In such a society, city officials must be creative and resourceful to convince and educate the property developers that providing pedestrian pathways and facilities will work for them, rather than against them, by increasing the value and demand of their development. Their brand will also benefit from providing pedestrian facilities as the developers will be seen as community-friendly and sustainability-conscious.

The issue of education is not unique to property developers. The communities themselves must be educated and trained on proper behavior while walking and the importance of observing safety (Pei-Sung Lin et al., 2019). A list of dos and don'ts while walking helps to educate and remind the communities of the different type of hazards on the pathway that they may come across as well as their associated risks. The list can be in the form of pamphlets or even posted as sign along the pathway. Notwithstanding the list, the best form of education to encourage safe walking practices is when proper pedestrian knowledge and skills are integrated into the school education curriculum and system. Unfortunately, the incorporation of this subject is difficult to implement as it requires concerted effort from many parties and agencies. Teachers must be trained, curriculum must be redesigned, skills and behaviors must be assessed, and so many other issues surrounding formal education and training must be taken care of. Due to the complexities of school curriculum design/redesign, the education and training on pedestrian safety have taken the informal route. Some corporations, as part of their corporate social responsibility (CSR) programs, have taken the tasks and responsibilities onto themselves to provide the education that is so critical for the communities, especially for children and senior citizens. The success of such CSR programs may be enhanced with the participation of nongovernmental organizations and social activists. When such programs exist, sufficient incentives (e.g., subsidies, tax reliefs, etc.) must be provided by the local government, not only as a form of formal recognition but also to encourage more of such programs.

Unfortunately, there is a clear possibility that no amount of education, motivation, and promotion is sufficient to encourage or induce behavioral change. In this situation, local government should redesign streets to make them safe with existing pedestrian behavior and, if that is not practical, should introduce strict enforcement through effective policing to reprimand offenders who flaunt safety rules—be it pedestrians or motorists. For examples, motorcyclists who fail to observe no parking rules on pedestrian pathway may have their motorcycles confiscated by the city and the owners reprimanded by paying fines. Similarly, pedestrians who jaywalk should be fined as a form of hard education to force behavioral change. If we want to reach vision zero, as discussed in a different article in this encyclopedia, we need to combine engineering measures with enforcement and education. Not least is education needed to change people's attitudes to give priority to safety over mobility.

All the earlier issues on ensuring pedestrian safety are complex issues that consistently plague city officials. Nonetheless, they are not without solutions nor are they impossible to achieve. These issues can be solved with active cooperation and participation of all stakeholders for the mutual benefits of the city. Also, to be successful, there must be a strong political will to ensure that cities are safe for its people to walk.

Introduction

Walking should be considered as a valid solution to reduce the variety of problems raised by the modern car-oriented society. It is a green transport option due to no air and noise pollution involved, useful to tackle traffic congestion and parking issues, and overall more affordable and reliable than motored modes. As an active transport mode, for older people walking is at the same time a transport option and a recreational activity that provides physical activity, with consequent benefit to individuals' health and quality of life (O'Hern and Oxley, 2015; Tight, 2016).

Nonetheless, walking is not an easy activity to undertake during later life. Older pedestrians are sometimes referred as extra vulnerable road users, since all pedestrians are vulnerable to injury, and older people are even more so, due to their greater frailty and longer recovery time compared to younger people (O'Hern and Oxley, 2015). Indeed, they are over-represented in crashes at intersections, crashes when crossing at mid-sections of roads, especially on high-speed and wide or multi-lane ones (Oxley et al., 2004). Statistics from EU 27 countries show that the percentage of pedestrian fatalities is higher for those aged 65 years old and above than for any other age group, despite the number of fatalities decreased from 3459 to 2595 (25%) between 2007 and 2016. The high risk is particularly valid for those aged 80–84 years old, as the number of fatalities peaks for this age group. Moreover, the pedestrian fatality rate of older people is above the average and steadily increases from the age of 70 up to over 85 (European Commission, 2018). The United States present a similar situation, with 20% of all pedestrian fatalities (1165 out of 5903) that happened in 2017 involved people aged above 65 years old. Male older pedestrians aged 80 years old and above present the single highest fatality rate by age groups and gender at 4.55 pedestrian fatalities per 100,000 population, while the rate for the overall 65+ population is 2.29 (NHTSA, 2017).

Factors posing a risk to older pedestrians can be grouped into three main categories: (1) decline in health conditions, (2) built environment form and design, and (3) road crossing behavior.

Decline in Health Condition

It is recognized that mobility in later life is influenced by progressive changes associated with decline of health conditions. Unlike other transport modes (e.g., public transportation and car) that in some aspects can compensate for health impairments, walking can be more directly affected by deteriorating health functions (Siren and Hakamies-Blomqvist, 2005). Overall, decline in health affects sensory, physical, and cognitive functions.

Sensory Impairments

Sensory impairments are related to the loss or decline of visual and hearing functions. Older people experience these deteriorations as a consequence of advance aging, although, with considerable variation between individuals due to the heterogeneity that characterizes the older population. In general, sensory impairments are associated with the risk of falling, reduced perception of fixed and moving objects, problems in detecting approaching vehicles, and difficulties in distinguishing vehicles from other aspects of the road environment (Dunbar et al., 2004; Tournier et al., 2016).

Visual skills are required to perform some of the tasks associated with walking, such as navigating and movement detection. However, older people are more likely than other age groups to suffer from pathological age-related eye diseases, such as glaucoma, cataract or macular degeneration. Glaucoma affects peripheral vision, and the person experiencing it may be unaware of it, and difficulty in adapting to darkness. Pedestrian risks associated with this disease affect road crossing due to difficulties in detecting objects/obstacles not located straight ahead, poor adaptation to dark and detection of object/obstacles in such context, leading to a higher risk of falling and poorer self-reported mobility (Dunbar et al., 2004; Tournier et al., 2016). Presence of cataract affects dynamic and static visual acuity, contrast sensitivity, and difficulties in seeing in poor light. Suffering from cataract leads to difficulties in road crossing because of reduced ability in detecting objects, both fixed and moving, from the rest of the road. Moreover, this disease was found to be associated with risk of falling, self-reported difficulty in making distance judgments, depth perception, and navigating in dark environments (Tournier et al., 2016). Finally, macular degeneration causes blurred or distorted central vision and scotomas, with potential risk of falling, particularly in reduced light environments (Dunbar et al., 2004). Another visual impairment not linked to pathological age-related changes affecting pedestrian safety is the deterioration of visual motion sensitivity, which is found to affect road crossing decisions due to misperception of approaching vehicles at high speed (Tournier et al., 2016).

Hearing loss is frequent with advance aging, particularly for the older people aged 75 years and above. Hearing functions play an important role in pedestrian safety in terms of spatial detection and localization of objects and vehicles in the road environment. Older pedestrians with hearing impairment have difficulties at detecting approaching vehicles coming from behind them or while turning. Furthermore, hearing loss was found to affect sense of balance and consequently to increase the risk of falling, in addition to poor general mobility, physical health, and self-perceived sense of security (Dunbar et al., 2004).

Physical Impairments

Physical impairments are associated with age-related changes and decline in muscles strength and mass, bones frailty, and mobility of joints. Changes in strength and mass of leg muscles affect overall mobility in terms of walking speed, ability to maintain balance, and consequently, increased risk of falling (Oxley et al., 2004). In general, older people walk slower than younger people. Lower speed implies increased time required to cross a road and overall time to undertake a given journey (Asher et al., 2012). Similarly, physical impairments reduce head rotation movements while exploring the road environment before crossing a road, with increased risk of misjudging the evaluation of approaching vehicles.

The decline of leg strength reduces the ability to keep balance and to deal with losing balance circumstances. Indeed, older people react to loss of balance differently compared to younger cohorts and are less able to quickly recover their balance (Dunbar et al., 2004; Tournier et al., 2016). This is particularly valid when they have to cope with a secondary task while walking, or in case of suffering from sensory impairments at the same time. Therefore, older pedestrians are significantly exposed to risk of falling and the consequence of falling can be particularly serious, as they are more likely to be affected by fracture and need more time to recover than younger people (Dunbar et al., 2004). In this sense, suffering from low mass density and deterioration of bones can increase the consequences associated with falling (Dunbar et al., 2004; Tournier et al., 2016). Osteoporosis is a common systemic skeletal disease during later life, particularly among older women, associated with fractures and therefore risk of falls. Furthermore, osteoporosis is a cause of kyphosis, a postural disease that exaggerates the anterior curvature of the thoracic spine. Kyphosis affects general mobility due to the particular poor postural condition and increases the risk of falls and fractures. Moreover, it reduces the ability to avoid obstacles and climb stairs, together with visual exploration while crossing a road (Tournier et al., 2016). Likewise, arthritis is another common impairment among older people caused by inflammation of joints. Arthritis affects walking by restricting range of movements, and consequently balance, and by reducing strength and physical endurance (Oxley et al., 2004).

Cognitive Impairments

Cognitive functions also decline with advancing age. Typical age-related shortfall involves reduced performances in memory, speed, and accuracy, in addition to difficulties in spatial processing, planning, and selecting attention (Dunbar et al., 2004; Oxley et al., 2004; Tournier et al., 2016). Decline in selecting attention, executing function, and slower processing performances affect significantly multi-tasking operations. Selecting attention is a function necessary to bring information into focus and hinder inconsistent or unnecessary information. In this sense, older pedestrians report significant difficulties in dealing with situations requiring attention between more than one task, switching attention, visual search, and ignoring not useful information, especially while in movement. Risk of falling and difficulties in obstacle negotiation were found associated with loss of it (Dunbar et al., 2004). Similarly, decline in executing function was found to impact gait control and multi-task coordination, with consequent increase of risk of falling. To avoid so, older pedestrians compensate for their walking behavior by reducing their walking speed or avoiding potential distractions (e.g., talking with other people). Problems in multi-tasking operations are cause of increased risk of being involved in an accident at intersections, due to the complexity of junctions compared to other situations (Dunbar et al., 2004; Oxley et al., 2004; Tournier et al., 2016). Slow processing speed is among the factors contributing to difficulties in navigation. Moreover, it affects the decision-making process associated with road crossings by increasing curb delays (see Road Crossing Behavior section for further information).

Another necessary walking skill affected by cognitive impairments is the ability to spatially navigate in a determined environment. In general, navigation skills decline while aging and older people perform less efficiently than younger people in this sense

do. As a consequence, older pedestrians tend to commit more mistakes in finding way and take longer time in completing their walk. Decline in spatial processing and loss of memory are the two main functions impacting this skill. They both contribute in reducing the ability to navigate and orientate, particularly in an unknown context. Furthermore, older pedestrians have lower and less accurate performances in route learning and sequencing compared to younger people (Dunbar et al., 2004; Klencklen et al., 2012).

Built Environment Form and Design

The form and design of the built environment can also significantly affect older pedestrian safety. The reliance on private transport modes has contributed to the design of living environments around vehicular movement rather than human ones, with consequential difficulties for those relying on active transport modes (Matan and Newman, 2012). Urban sprawl and community severance are two phenomena affecting walking consequences of urban planning design. The former produces a dispersion of services and activities beyond a reasonable walking distance, while the latter creates a divisive effect on residential areas affecting the easiness to cross a road, street connectivity, walking ability, accessibility, and overall walking quality (Anciaes et al., 2016). In this sense, difficulties in crossing a road and associated risks of doing it are accentuated by the larger sections of road to cover. Older pedestrians are not able to cross safely because of their lower walking speed and therefore not being able to cross the road until an automobile reach their crossing point. Moreover, community severance creates a psychological barrier affecting walking quality by increasing self-perceived risk of being involved in a collision due to traffic volumes, speed, noise, and pollutant emissions associated with this phenomenon (Anciaes et al., 2016).

The design of the walking environment can also be a barrier for walking and a factor concerning older pedestrians' safety. Handling sidewalks is considered one of the most difficult tasks for older pedestrians, particularly with regard to obstacle negotiation and related risk of falling issues. This is particularly valid for those crossing environments that are not leveled and have steps (Tournier et al., 2016). The poor-quality design of footpaths and sidewalks regarding the presence of steps and pavements materials, such as the use of pebble stones or cobblestones, and general uneven and broken pavements, are all factors increasing the presence of obstacles while walking (Tournier et al., 2016). Similarly, sidewalks or nearby parallel walking paths are fundamental in order to separate pedestrians from the driving environment, but the presence of not lowered curbs at both beginning and end of footpaths can add further complications to road crossing tasks (Mitra et al., 2015; Rosenbloom, 2009; Wang et al., 2016). The presence of cars and scooters parked on, or obstructing, sidewalks, and cleanliness and lack of maintenance of footpaths are also associated with problems in obstacle negotiation and the risk of falling (Chen et al., 2015). Moreover, in contexts such as Northern countries, the presence along the pathway during the winter season of snow, ice, and mud resulting after both melt, is an additional barrier and factor of risk (Hjorthol, 2013; Rosenbloom, 2009).

Stumbling over an obstacle is considered one of the most common causes for falling. In a similar way, the task of avoiding an obstacle suggests an elevated level of risk, especially for those affected by cognitive impairments due to multi-tasking operations involved. Under such conditions, typical strategies that older pedestrians engage to negotiate with obstacles involve reducing walking speed and step length, keeping a large distance between themselves and other pedestrians and spending more time looking at their footsteps rather than straight ahead or for traffic (Dunbar et al., 2004; Oxley et al., 2004; Tournier et al., 2016). Design solutions can significantly facilitate walking and reduce the risk of being involved in accidents or getting injured. In this sense, implementations have to be particularly focused on reducing vehicle and pedestrian conflicts, especially those associated with crossing the road. Examples of such improvements include raised crosswalks, speed cushions about 10 m before the crosswalk, median islands, curb extensions, improved user-activated signal crossing devices such as puffin crossing with time regulated by sensors. Crosswalks should preferably never extend across more than one lane without having islands for resting, especially if top speeds are above 30 km/h.

The poor design of the built environment can also affect older pedestrians' self-perceived safety and older people tend to be particularly sensitive regarding this matter. Older people tend to avoid walking during particular times, such as during the night or generally when it is dark, or in areas of cities that are perceived as dangerous. A lack of adequate street lighting and the presence of dark areas contribute to preventing older people from walking, especially for the potential presence of people—either groups or individuals—hanging out in the streets (Mitra et al., 2015; Wang et al., 2016).

Another factor related to road design affecting older pedestrians' self-perceived safety is the suggestion of sharing the walking environment with other road users, especially with motor vehicles. Apart from the risk of being involved in car accidents, older pedestrians perceive that drivers fail to acknowledge the rights of other road users. Typical examples in this sense are represented by people parking cars and motorbikes on the sidewalks and car doors opening without paying attention to passing pedestrians. These negative behaviors are exacerbated in the case of narrow sidewalks (e.g., obstructing the passage) or when the elevation of the sidewalk is not sufficient to discourage car parking (Oxley et al., 2004). Finally, older pedestrians report safety problems in shared cycling/pedestrian environments. Dedicated shared cycle and walking lanes are a well-acknowledged solution to improve the safety of cyclist and pedestrians, and overall to incentivize active travel. However, striping may not be sufficient to keep cyclists out of the walking part and it is therefore common to use smooth pavement for the bicycle part and paving stones or similar material for the pedestrian part. This is also not a good solution since it leads to hard and uneven walking surfaces as discussed above. Nonetheless, continuity of cycle lanes and footpaths and problems of space invasion are perceived as a factor of risk, particularly regarding bicycle speed by younger users (Oxley et al., 2004; Vine et al., 2012).

Road Crossing Behavior

Crossing a road is among the situations in which older pedestrians face high risks to be injured or killed, as the most dangerous accidents happen while undertaking this task. Crossing a road is a complex situation involving several stages (Oxley et al., 2004). Older pedestrians have to identify a suitable place to cross the road while approaching the curb and they may have to explore the crossing environment by scanning potential approaching vehicles. Then, even though they, in most cases have the right-of-way, have to judge traffic gaps, and determine the right time to leave the curb to cross the road.

Explorative Behavior at the Crossing Environment

Not having seen an approaching vehicle that hit them while crossing a road is among the most reported causes by older pedestrians of road accidents (Dunbar et al., 2004). Consequently, identifying a suitable crossing point while approaching the curb is fundamental for older pedestrians in order to explore the road environment before crossing safely (Tournier et al., 2016). The majority of the studies investigating pedestrian crossing reveal that young and older people present a similar explorative behavior at crossing points in terms of number of head movements to check for traffic. This was found particularly valid in presence of traffic signals. Overall, older people tend to look slightly more often than younger people, especially when crossing roads with two-way traffic. However, they were found to make a smaller rotation of their head due to physical impairments, and therefore assess less efficiently approaching vehicles (Dunbar et al., 2004). In absence of traffic signals, older pedestrians tend to be more thoughtful and have a more conservative approach. The evaluation of road crossing opportunities tends to decline with advancing age and older pedestrians are likely to pause more at the curb before crossing and more often turn their heads in visual exploration, both before and while crossing the road (Oxley et al., 1997).

Gap Judgment and Acceptance

Gap acceptance is traditionally defined as the distance of a vehicle in movement from the pedestrian at the time of the first step while undertaking the action of crossing the road (Oxley et al., 1997). Where automobile drivers have the right-of-way by legal code, or de facto take that right, gap judgment by pedestrians is a necessary skill for older pedestrians in order to identify opportunities to cross the road in a safe way. Gap judgment is a particularly complex skill because older pedestrians have to take into account vehicles' speed and distance and time of arrival to the other side of the road, in addition to their own walking speed (Oxley et al., 2004). It is therefore imperative to change the behavior of drivers so that, at least at marked crosswalks, it is the automobile drivers that look for gaps in between pedestrian before they proceed rather than the traditional assumption that drivers have priority to all space.

Older pedestrians perform less safe and less efficient than younger people in terms of making gap judgments (Dunbar et al., 2004). Indeed, they, on average, do not accept short gaps as their younger counterparts, but at the same time, they take longer to cover the distance needed to cross the road. Thus, they have a tighter fit between crossing completion and the vehicle crossing their path, with consequent reduction in safety margins. Furthermore, older pedestrians have more difficulties in evaluating speed and they therefore more frequently use distance of an approaching vehicle as a determinant for when stepping off the curb (Oxley et al., 1997). Nevertheless, they also have more difficulties evaluating distances than younger people. Hence, they feel safer and prefer accepting gaps where the approaching vehicle is further away, but at the same time they may underestimate the speed of the vehicle, implying that it will arrive later than expected and accept gaps that are objectively dangerous (Oxley et al., 1997). The solution to improving safety is to secure that vehicle speeds are low. Today, many jurisdictions allow crosswalks on roads with up to 50 and even 60 km/h speed limits. Where older pedestrians or children may cross a street, crosswalks should not be marked if top speeds are above 20 km/h as that can lead to the earlier-mentioned unfavorable situation that it is pedestrians that look for gaps between cars rather than the opposite. If speeds are above that, signalization or stop signs can be used.

Curb Delay

Curb delay is an important factor explaining risk when jaywalking is occurring or even at crosswalks when automobile drivers take the right-of-way away from pedestrians. It can be defined as the time since when the last vehicle passed a pedestrian waiting to undertake the first step toward the road to be crossed (Oxley et al., 1997). Overall, older pedestrians tend to leave the curb later than younger people, with time delay identified in just under 1 s. In contrast, younger people were found to leave the curb slightly before the passage of the last vehicle (Oxley et al., 1997). Three different reasons can explain this approach difference. As previously mentioned, older people tend to be more cautious and have a more conservative attitude within the road environment. In this sense, they are more likely to pause more time at the curb, especially in case it is dark or if they have to cross a road with more than one lane (Dunbar et al., 2004). Another explanation is that older pedestrians might adopt an inefficient strategy to cross the road compared to younger people. As younger people were found to not wait for the last vehicle to pass before starting to cross the road, this might imply that they perform better in considering opportunities to cross the road (Dunbar et al., 2004; Oxley et al., 1997). Finally, increase in curb delay might be associated with slower time reaction, decision-making, and motor coordination. Crossing the road is a complex task and decline in physical and cognitive skills can reduce responding time performances, especially in complex traffic situations (Oxley et al., 1997).

Crossing the Road

Let's start with looking at jaywalking pedestrians or pedestrians crossing where drivers do not yield to them. Once older pedestrians have visually investigated the road environment and accepted a reasonable gap between them and approaching vehicles, they are ready to cross the road. Oxley et al. (1997) identify two different type of crossing styles can be identified based on the approach undertaken while crossing the road. Non-interactive crossers are identified as those pedestrians employing a safer approach and waiting until the road is clear in both directions to cross in one single action. In contrast, at locations that have more than one lane from the curb to refuge island, interactive crossers employ a less safe approach and negotiate their crossing by pausing, usually midway, modifying their walking speed and weaving through traffic. In their turn, interactive crossers can be further classified into three sub-groups: those who interact with the nearside traffic only, those who interact with the far side traffic only, and those who interact with both directions of traffic while crossing.

Older pedestrians usually belong to the interactive group, particularly by interacting with the far side of the road. Adopting this approach highlights again the complexity that crossing a road has for older pedestrians. In this light, they might encounter multi-tasking difficulties in evaluating the traffic in both directions and quickly react and adapt to the traffic conditions. As a consequence, some older pedestrians consider crossing the first half of the road without concern of the remaining half, reducing their safety margins significantly (Oxley et al., 1997). Reduction in walking speed is another factor characterizing interactive crossing. Older pedestrians might start crossing while the road is clear, but due to low walking speed, the road turns busy by the time they reach the middle of it (Dunbar et al., 2004; Oxley et al., 1997).

Decrease in walking speed can also affect crossing a road in presence of a traffic light. Several older pedestrians report difficulties and anxiety associated with the feeling of not being able to complete the crossing within the allocated time (Tournier et al., 2016). Indeed, the walking speed internationally used to base pedestrian crossing time is currently 1.2 m/s. Several studies report that older pedestrians struggle to reach such speed and findings suggest that reducing the average speed to 0.8 m/s might be more appropriate and would allow them to cross the road with higher safety (Asher et al., 2012; Oxley et al., 2004). It should also be noted that in most jurisdictions, any road user who enters on green has the right of way over perpendicular traffic until they have cleared the intersection. However, if a road has multiple lanes, a slow-walking pedestrian may not be visible to drivers and a driver may by mistake start up when the signal turns green for them. Educating drivers that they have to look for pedestrians—and not enter the intersection—in such situations is another part of ensuring safety.

In conclusion, it is of utmost importance that streets and roads where older pedestrians cross at level are kept narrow and have low speeds. Preferably, all roads should be built in such a way that older people and children can walk safely along them and cross them without having fear of getting hit by vehicles. If streets and roads are built that way, people of all age groups and with different handicaps will be reasonably safe.

Historical Perspective

Blind pedestrians or visually impaired have been traveling independently for millennia. For much of this time, the two primary tools available to assist in their travel were the help of other people, often as guides, or the use of some sort of walking stick. In the 1920s, dog guides became a mobility option for people who are blind and since the 1940s; the walking stick tool has been formalized as the modern white cane (sometimes referred to as a long cane and previously referred to as a typhlocane). While traveling with a sighted partner can allay many safety concerns, many blind people are not able to or prefer not to rely on other people for their travel needs. So, it is often necessary for them to travel independently. To do so, a range of tools (beyond using a dog guide or long cane) and techniques have been developed to reduce risk and increase safety.

People who are blind have been able to become accomplished independent travelers even before the advent of modern tools. James Holman, who lived from 1786 to 1857, is an excellent example of the degree of independent travel possible by someone who is blind, even under the most difficult circumstances. At a time when most of the blind people were expected to remain at home and be cared for by others, James Holman traveled the world alone, becoming an explorer, adventurer, and writer and eventually traveling to every inhabited continent. However, for most people who are blind, the scope and range of independent travel has greatly increased with the advent of modern tools, infrastructure, and instruction of travel techniques.

Orientation and Mobility

In the United States, there are approximately 65,000 legally blind children and youth and approximately 7.7 million adults over the age of 18 who have some sort of vision loss (APH, 2016; Erickson et al., 2017). When referring to a person as being “legally blind,” this means that the person’s vision is 20/200 or worse (where 20/20 is typical or normal vision) or they have a severely constricted field of view. Not all of these 7.7 million people would require the use of a dog guide or cane to get around. For example, only about 2% of blind people (about 10,000 people) use a dog guide. However, any degree of vision loss will impair a person’s ability to access information, such as street signs or to respond quickly to threats in the environment, such as vehicles running red lights at an intersection.

The set of techniques and strategies taught to pedestrians who are blind to facilitate independent travel is called orientation and mobility (O&M). The field of O&M has developed travel techniques, often expanding on natural tendencies and abilities of the people who are blind. For example, a powerful tool for blind people is using reflected sound to get a sense of what is around them. This is a skill that can be taught and refined, especially if a person becomes blind later in life and has never had to develop this skill before. The primary mobility tool, the long cane, has been improved through the use of new materials and the development of specialized tips. However, in terms of mobility tools, a greater advancement has been the development of GPS technologies and phone-based apps that allow blind people to access more information about the world around them and use this information to guide them in their travel.

Some of the main impacts on the mobility for people who are blind or with low vision is that they will tend to travel more slowly, they often need to access information tactually or through hearing (which might be less precise), they may experience more stress and anxiety when traveling, and there is an increased chance that quickly moving features of the environment will increase risk for them. For example, a signal that changes quickly at an intersection leaving pedestrians without enough time to cross the road; and vehicles that speed through an intersection, leaving little chance for auditory detection. Unfortunately, there are very few statistics on how often people who are blind are involved in accidents. In 2017, 5,977 pedestrians were killed in the United States (NHTSA, 2018). It is estimated that there are at least 70 legally blind pedestrians involved in accidents annually. Although the act of traveling without vision seems inherently more risky than traveling with vision, there are evidences that pedestrians who are legally blind are less likely to be killed or hospitalized as a result of being hit by a vehicle than a sighted pedestrian. This is most likely because there are fewer blind pedestrians, they tend to travel less, and they often use transportation modes, such as paratransit that limit exposure to the potential for serious conflicts with vehicles. Note, however, that these accident statistics are based on pulling information from

databases where disability status is not always noted. Further, blind pedestrians might be at increased risk for minor injuries from vehicles that would not show up in databases, such as the Fatality Analysis Reporting System (FARS) in the United States.

Challenges to Independent Travel

With a greater range of useful and far reaching tools for assisting in the safe travel, two of the greatest limiting factors to safe travel for blind pedestrians are public sentiment and the travel environment. Sighted parents are understandably concerned about the safety of their blind children but this can sometimes lead to over protection and a lack of sufficient movement and exploration when children are young. Lack of exploration when young can lead to lesser degrees of independent travel when older. Blind children need to be encouraged to move and explore, the same as any other child. As they grow, they will be introduced often through the work of professionals, such as O&M instructors, an array of tools and techniques that will support expansion of their independent mobility. But the blind child who is allowed to explore his or her environment will also develop their own compensatory strategies for getting around as they develop a sense of the larger world around them. Nevertheless, there are parents or general members of society who do not think people who are blind can or should travel on their own. Many people who are blind will chafe at these attitudes and have to deal with members of society that do not understand how independent they can be. Given that this is still a common perception, many aspects of the world and built environment are not designed with the intent of accessibility by all people with disabilities. As such, the greater challenge is learning how to effectively navigate the modern travel environment.

Risk in the Modern Travel Environment

The modern travel environment is full of fast moving vehicles, streams of people, and an array of signs, signals, and obstacles that might not be easily perceived or dealt with by someone who is blind. Traditionally, in the urban built environment, traffic patterns have been a consistent and useful cue used by blind pedestrians to guide their travel. Consistent traffic movements can remind a blind pedestrian how close they are to the street, whether they are approaching an intersection, and what sort of traffic control exists. One- and two-way traffic can also help indicate a pedestrian's position within a network of streets. Also, blind pedestrians use the sudden surge of parallel traffic beside them at an intersection as a strong cue for when they can cross a street (Fazzi and Barlow, 2017). Consistency and regularity of environmental characteristics and traffic patterns have been foundational in limiting the risk for blind pedestrians. Being able to predict what will happen in an environment and what different characteristics and events mean allows a blind pedestrian to more effectively deal with other aspects of the travel environment. For example, a pedestrian will encounter an assortment of poles, signs, trashcans, newspaper boxes, and other "street hardware" when walking along a downtown street. Many of these elements change from time to time and are certainly not consistent block to block. But this level of uncertainty introduces low levels of risk for a person using a cane or dog guide since the pedestrian remains on the sidewalk.

When inconsistency exists in curb height, the presence and placement of wheelchair ramps, block length, driveway interruptions to the sidewalk, the presence of medians, and especially the presence of actuated intersection control, risk is increased and safety is reduced for blind pedestrians. When wheelchair ramps first became widespread in the United States, it was noted that blind pedestrians began walking into the street without being aware of it. Tactile walking surface indicators, known as detectable warnings in the United States, were devised and installed at the bottom of wheelchair ramps in order to warn blind pedestrians that there was a transition from the walking surface to the road surface (Barlow et al., 2010). However, as ramps and detectable warnings have become more prevalent, many pedestrians have developed the misperception that detectable warnings indicate where a person should stand in order to cross the street. While this is often true, it is not always true. An apex ramp on a given intersection corner (where the ramp is placed in the middle of the corner, between two crosswalks, facing diagonally into the intersection) is one case where detectable warnings on the ramp would not be where a pedestrian should stand in order to cross either street. Further, misunderstandings of the intent of detectable warnings have led to incorrect installation of them by city engineers. Blind pedestrians cannot take a line of direction from the set of truncated domes used as detectable warnings. Therefore, aligning a rectangular section of these truncated domes with a crosswalk does nothing to help with a blind person's alignment but might hinder an accurate perception of the true boundary between the walking surface and the road surface.

One situation, where tactile warning surfaces are of particular importance, is on the edges of transit platforms. Whether in a metro system, an elevated train system, or a regular train system, when a mass transit vehicle enters a station where passengers get on and off the cars from a station platform, the edge of the platform needs to be clearly demarcated with a tactual warning (Architectural and Transportation Barriers Compliance Board, 2016). Truncated domes work well for this warning. Since subway or train cars are always situated at the same spot when a train pulls into a station, some mass transit systems have included tactual walking surface indicators to lay out tactually where pedestrians should line up in order to board the next train. In this way, both sighted and blind pedestrians are organized so that confusion is reduced and safety is increased.

While inconsistency in the built environment has increased risk and reduced safety for blind pedestrians, a recent change that has had perhaps the largest negative impact on safety has been the advent of actuated intersections. Historically, a blind pedestrian could approach an intersection and, since the traffic patterns tended to be regular and consistent, listen to these patterns and soon have a good idea of when an appropriate time to cross the street would be. However, the addition of more traffic movements, such as protected left turn phases and combinations of protected turning and straight through movements at intersections increases the level

of difficulty for a person who cannot see to understand the traffic patterns simply by listening. Larger intersections with multiple traffic movements can often trick blind pedestrians into thinking that they are hearing a parallel surge of traffic (Barlow et al., 2010). For example, at large intersections, a vehicle coming toward a pedestrian from the far parallel lanes and turning left to cross the pedestrian's path can sound like a vehicle that is going to continue moving on a parallel path since it must travel so far forward before beginning its left turning movement. If the intersection is actuated so that the length or presence of a given traffic movement depends on what traffic exists, then the traffic patterns might be very different from one time of the day to another or even from one traffic cycle to the next. This level of complexity and uncertainty increases the risk for blind pedestrians.

To some extent, this uncertainty can be reduced by the provision of accessible pedestrian signals. These are audible indicators of when the visual walk signal is lit. If an intersection is outfitted with accessible pedestrian signals, then this gives more information to the blind pedestrian about when an appropriate time to cross exists. However, it does not eliminate risk entirely. Uncertainty regarding traffic patterns would still exist and now a pedestrian would have to determine whether a pushbutton is at the intersection to activate an accessible pedestrian signal, then find the button and realign to make their crossing. Further, any inconsistency in how accessible pedestrian signals and pushbuttons are installed on different intersection corners can add to the uncertainty and confusion experienced by a blind pedestrian.

It seems that many modern developments in urban design end up making travel more difficult for blind pedestrians. Roundabout intersections can be problematic since the rounded walkways and roadways often make finding a crossing place harder (Barlow et al., 2010). Once a crossing place is found, the lack of traffic control means that pedestrians can only cross the street in a gap in traffic or in front of a yielding vehicle. However, the acoustic surroundings often make it hard to determine whether a vehicle is approaching, how far away it is, and if a vehicle has yielded. While smaller roundabout intersections are often crossable with training and perhaps minor engineering modifications, newer intersection designs, such as the diverging diamond interchange have recently introduced entirely new challenges to accessibility for blind pedestrians. While it would greatly reduce risk for all pedestrians to limit all roadways at uncontrolled crossings to one lane in each direction, with a refuge island between the lanes, such a situation is unlikely to become the norm in the United States where traffic flow is often given priority over pedestrian safety.

Another feature of the modern travel landscape that has increased risk for blind pedestrians is the advent of quieter vehicles. While many people think of this issue as relating to hybrid and electric vehicles, many internal combustion engine vehicles have also become so quiet that blind pedestrians can have difficulty in hearing whether a vehicle is near them or what that vehicle is doing. Blind pedestrians rely largely on listening to traffic to maintain a sense of position and safety, especially in urban areas. Reducing the sound level of individual vehicles makes those vehicles much more likely to surprise a pedestrian, potentially in a catastrophic manner. This is especially true when there are louder vehicles helping to mask the sound of the quieter vehicles. There are efforts being made to add sound to hybrid and electric vehicles so that they are not entirely silent but little is known about the best sounds to add and the impact of these sounds on the abilities of blind pedestrians to hear and react appropriately to vehicles equipped with the added sounds.

However, even with sounds added to quieter motor vehicles, there will remain a potential threat to blind pedestrians from bicycles. Bicycles generally are very quiet but can move very rapidly and often share space with pedestrians. Cyclists operating on sidewalks will sometimes weave between pedestrians, but can also have an expectation that pedestrians will move out of their path, if given warning, such as from a bell. A blind pedestrian, however, suddenly hearing a bell quickly approaching from an unanticipated direction, will not be able to move out of the way so quickly. Where there are bicycle lanes on the side of the roadway, cyclists often have a greater expectation of the right of way in that lane. This means that a quickly approaching cyclist may have trouble stopping for a blind pedestrian stepping out in front of their path as the pedestrian crosses the street. Since bicycle lanes are often not demarcated with a tactual indication, a blind pedestrian might not be aware of the potential threat. Some cities are experimenting with a slightly raised edge to the sides of bicycle lanes so that bicycles can easily ride over the boundary but blind pedestrians can also feel that there is a boundary they need to be aware of.

An upcoming change to the modern travel environment is the increase in automated and connected vehicles. There is very little known about how this movement will impact the mobility of blind pedestrians. Much of it depends on how automated and connected vehicles are introduced. If a given municipality introduces system-wide use of connected vehicles including buses, ride share, and other mass transit systems, and if that municipality designs the system so that individuals with disabilities are able to interact with the system effectively, then the automated and connected vehicle movement might very well improve mobility for blind pedestrians. If automated vehicles are designed in a way that would allow operation by a blind person, the opportunity for that person to get into a vehicle and go where they want, when they want, would greatly improve their mobility options (Owens et al., 2019). However, although much has been touted about how automated vehicles will remove the human error factor in driving and make vehicle-pedestrian interactions safer, there has not been evidence thus far that this utopia is easily achieved. The level of technological sophistication that would be needed to allow a blind person to operate a vehicle safely through city streets seems to be many years in the future. That being said, current technology, such as automatic braking and pedestrian detection should improve safety for all pedestrians, including those who are blind. As the principle cause of pedestrian fatalities is a failure of drivers to yield, having more vehicles that will brake automatically for pedestrians should improve the general safety landscape. It is interesting that these developments are occurring at a time when the United States is seeing an increase in pedestrian fatalities.

In general, increasing consistency in the travel environment will tend to increase safety for blind pedestrians. As long as attention is made to making public spaces accessible, if the modifications are consistent, pedestrians are able to figure out the rest. An event where this becomes critical is during times of emergency. When other people are panicking or there is smoke or fire or loud noises, the rush of people and ensuing chaos can play havoc with any pedestrian's orientation. A blind pedestrian can be at a greater

disadvantage in this situation, as emergency measures are not made accessible to them. Flashing lights do not help a blind pedestrian. Also, verbal announcements on a loudspeaker that are not linked to landmarks that make sense to a blind pedestrian are not helpful. In general, having emergency lights and audible signals that lead people along egress routes have been shown to be the most helpful in getting all pedestrians, including those with visual impairments, out of harm's way and to safety in an emergency.

What is Photo/Video Traffic Enforcement?

Photo/video enforcement refers to the use of cameras to help enforce traffic regulations. It allows for the detection of violations without the need for human observers at the site. It is a useful supplement to standard enforcement because traffic volumes exceed the availability of officers to enforce traffic regulations. In addition, in congested areas and at intersections, there may be no place to safely pull over violators.

Examples of photo/video enforcement include photo radar for speed enforcement, red light cameras for traffic signal enforcement, virtual weigh stations for commercial vehicle weight enforcement, and automated highway toll systems. The technology can also be used to detect drivers who block intersections or fail to stop at a stop sign, drive past a stopped school bus, or disobey a railroad-crossing signal (Decina et al., 2007).

How Does Photo Enforcement Work?

Violations can be detected by sensors in the roadway, sensors on roadside architecture, and sensors within the vehicle. Most speed cameras measure the speed of a vehicle at a single spot. If a vehicle is traveling faster than a predetermined speed, the date, time, location, and speed are recorded along with photos or videos of the vehicle. Section control is an enhancement of photo speed enforcement that measures average speeds over a certain distance. Cameras located at two or more points record all vehicles that pass them. Automatic license-plate recognition is used to match individual vehicles so that average speeds between the two points can be calculated. Section control has been used to enforce speed limits in Australia, Austria, Italy, Netherlands, Norway, and the United Kingdom.

Red light cameras automatically photograph vehicles that go through red lights. The cameras are connected to the traffic signal and to sensors that monitor traffic flow. The camera captures images of any vehicle that doesn't stop within a given time after the light switches to red. Cameras record the date, time of day, time elapsed since the beginning of the red signal, vehicle speed and license plate.

Speed-on-green/red light cameras can detect both vehicles running red lights and vehicles speeding through intersections. They have been used in Belgium, Canada, and the United Kingdom.

The History of Photo Enforcement

The first speed enforcement camera was manufactured by a Dutch company Gatsometer BV, in 1964. They followed up with a red light enforcement camera 2 years later. By 1973, limited speed camera programs had been tested in Switzerland and Germany, and limited red light camera programs were established in Israel and Sweden.

A trial run of speed cameras began in Victoria, Australia in 1985. The community of Paradise Valley in the United States began using a single speed camera in September of 1987. Speed cameras came to Canada and Norway in 1988. By 1999, there were speed camera programs in Finland, Hong Kong, the Netherlands, Sweden, and the United Kingdom, and by 2009 they were common throughout the Western Europe (Delaney et al., 2005).

In 1979, several red light cameras were installed in Perth, Australia. Singapore began a program in 1986. Red light cameras were installed on the London ring road in 1990, and New York City launched its red light camera program in 1994. Red light cameras became especially prevalent in the United States. By 2011, there were more than 500 communities in the United States with red light camera programs.

Surveys conducted in jurisdictions with photo enforcement programs show a majority of drivers support them.

A 1991 survey of drivers in Victoria, Australia reported 79% support for the speed camera program. In the United Kingdom, 70% of drivers polled in 2001 said they favored speed cameras. Support was highest for cameras in school zones and at locations with a history of frequent crashes. In the Netherlands, 75% of drivers expressed support for automatic speed enforcement. About 70% said they would stick to the speed limit if enforcement occurred a few times per year, and almost all said they would stick to the speed limit if it were enforced every week.

In the US state of Arizona, 63% of drivers surveyed prior to the start of automated enforcement said speed cameras should be used on an urban freeway where camera enforcement was planned. After speed cameras were operational, 77% of drivers supported their use. A 2017 US national survey of drivers, ages 16 and older indicated that 48% supported the use of speed cameras on residential streets.

A 2001 Canadian national survey reported 65% support for the use of speed cameras in school zones, but only 39% support for speed cameras on highways. Women and older people were more likely to support photo enforcement.

A 2011 survey of drivers in 14 US cities with red light camera programs reported a 66% approval rate. A companion survey in Houston, a city that had just cancelled its red light camera program, found support for cameras still at 57% (McCartt and Eichelberger, 2012). However, 28% of those surveyed in Houston strongly opposed the cameras compared with only 18% of those in the other cities.

Enforcement cameras can be either hidden (i.e., covert) or in full view (overt). Surveys of drivers in New Zealand, where both types have been used, found that 21%–27% thought the cameras should be hidden while 15%–26% thought they should be in full view.

Photo enforcement programs have faced controversy in a number of countries. Common complaints are that photo enforcement is stricter than standard police enforcement, that there is no opportunity to explain the circumstances of the offense, and that the goal of the program is to make money rather than to improve safety. Such complaints have led to loss of support in some communities, resulting in either any change to the programs or cancellation of the programs.

The Effects on Driver Behavior

As with other forms of enhanced traffic enforcement, photo enforcement changes driver behavior, at least while the enforcement is in effect. In 1973, when speed cameras were put in place on a relatively dangerous section of the German autobahn—with a speed limit of 100 km/h—speeds in the left lane decreased by about 20 km/h. Within 6 months of speed cameras being introduced in Victoria, Australia, the number of drivers exceeding the 60 km/h speed limit by more than 15–20 km/h decreased by 50%. A similar reduction was seen for drivers exceeding the speed limit by more than 30 km/h. In British Columbia, Canada, the 1996 speed camera program was associated with a 3% reduction in mean speed on a section of roadway with an 80 km/h limit.

Photo speed enforcement has been shown to reduce speeding on a wide variety of roads. Speed cameras were tested on 2-lane rural roads in the Netherlands in 1991. The proportion of drivers exceeding the 80 km/h limit was reduced from 38% to 11%. The mean speed declined from 78 to 73 km/h and the 85th percentile speed declined from 87 to 79 km/h.

In 2001, a speed camera program was initiated in Washington, DC. On urban streets with speed limits of 25–30 mi/h, mean speeds declined by 14%, and the proportion of vehicles exceeding speed limits by more than 10 mi/h declined by 82%. In 2006, speed cameras were temporarily installed along a 65 mi/h highway in the US state of Arizona—the proportion of vehicles exceeding speed limits by more than 10 mi/h declined by 88%. Mean speeds declined by 5–7 mi/h while the cameras were in place, but rebounded after the cameras were removed.

A 2010 review examined 35 studies from various countries (Wilson et al., 2010). The authors concluded that speed cameras—including fixed, mobile, overt, and covert devices—cut average speeds by 1%–15% and the percentage of vehicles traveling above the speed limits or designated speed thresholds by 14%–65% compared with sites without cameras. There is some evidence, however, that drivers slow down at camera sites, then speed up after passing the sites (sometimes called kangaroo driving) (Hoye, 2014).

A study of automated section speed control on an 80 km/h road in Norway reported a reduction in the mean speed from 77 to 74 km/h in the direction monitored by cameras. The percentage of vehicles exceeding the speed limit decreased from 37% to 22%. In the opposite direction (without camera monitoring) there was no change in speeds.

An evaluation of red light cameras installed at five intersections in Stockholm during the 1970s reported essentially no change in red light running behavior. However, there was little effort to inform the public of the enhanced enforcement. General deterrence of aberrant driving typically is achieved through posted signs and public information campaigns advertising the enforcement program. When Singapore began its red light camera program in 1986, warning signs were placed upstream of each camera intersection. Red light running rates at these intersections were 42% lower during the first 2 years of the program compared with the prior 2 years.

The red light camera program in New York City was set up similar to that in Singapore. The number of red light violations issued per camera per day dropped steadily from 30.8 in 1994 to 7.8 in 2015. Studies in the US states of California and Virginia reported reductions in red light violation rates of about 40% soon after the 1997 introductions of red light cameras (Maccubbin et al., 2001). The effect was evident at both camera-equipped intersections and at nearby signalized intersections not equipped with red light cameras (i.e., spillover or halo effect).

A 2014 study in Virginia also found significant reductions in red light violations at camera intersections. These reductions were greater the more time had passed since the light turned red. Violations occurring at least a half second after the light turned red were

39% less likely than would have been expected without cameras. Violations occurring at least 1 s after were 48% less likely. Reviews of international red light camera studies concluded that cameras lower red light violations by 40%–60% (Retting et al., 2003).

A study of speed-on-green/red light cameras in Winnipeg, Canada concluded that the cameras reduced red light running behavior by 21% and speeding behavior by 19% (Vanlaar et al., 2014).

The Effects on Roadway Crashes

Most studies worldwide have reported reductions in crashes associated with speed camera programs—especially the more serious crashes. After Norway instituted a speed camera program in 1988, there was an associated 20% reduction in injury crashes and 12% reduction in property-damage-only crashes on photo-enforced rural two-lane roads (Elvik, 1997). The speed cameras on a highway in British Columbia, Canada were associated with a 16% reduction in all crashes. A study of speed cameras in Hong Kong reported reductions of 23% for injury crashes and 66% for fatal crashes.

A study of 62 fixed speed cameras on 30 mi/h roads throughout the United Kingdom concluded that the cameras were associated with a 25% reduction in injury crashes. However, the researchers estimated that only 20% was attributable to reductions in speed, while the other 5% was due to traffic diverting away from the cameras (Allsop, 2010). The photo speed enforcement of the 80 km/h beltway around Barcelona, Spain, was associated with a 30% reduction in injury crashes. However, the enforcement that began 2 years later on Barcelona's 50 km/h arterial roads did not have any clear effect.

A study of France's speed camera program found that the July 2002 announcement of the initiative, which was widely covered in the media and included not only the introduction of cameras but also increased penalties for traffic violations and the creation of new traffic offenses, was associated with a 12% drop in the fatality rate. When the cameras became operational, there was an additional reduction of 10%, and that effect persisted over time. The rate of nonfatal injuries also declined after the announcement and in the first month of the program, but, unlike the effect on fatalities, the effect on injuries diminished over time.

A speed camera program began in Lisbon, Portugal in 2007. Injury crashes declined by 54% within the first few years. However, crashes began to increase after that, possibly due to familiarity with the system, malfunctioning equipment, and insufficient sanctions of violators.

A speed camera program in the US state of Maryland was associated with an 8% reduction in the likelihood that a crash on a camera-eligible road was speeding-related and a 19% reduction in the likelihood that a crash involved an incapacitating or fatal injury.

A 2010 review of 28 speed camera studies reported reductions of 8%–49% for all crashes, 8%–50% for injury crashes, and 11%–44% for crashes involving fatalities and serious injuries. Reviewed studies with longer duration showed that these trends were either maintained or improved with time. A 2014 meta-analysis concluded that speed cameras reduce all crashes in the vicinity of cameras by 20% and fatal crashes by 51%. However, the crash effects are no longer evident beyond 1 km downstream of the cameras. Section control was estimated to have an even greater effect—reducing all crashes by 30% and serious/fatal crashes by 56%.

The early studies of red light cameras in Australia yielded mixed results with regard to their effect on crashes. For example, a study of red light cameras in Sydney during 1986–91 reported a 26% reduction in injury crashes and an 8% reduction in crashes overall. A study in Adelaide during 1983–93 reported a 20% reduction in injury crashes, but a 2% increase in crashes overall—including increases in both rear-end and right-angle crashes. Right-angle crashes (i.e., front-into-side) are the crashes most closely associated with red light running (Aeron-Thomas and Hess, 2005).

A study of red light cameras in London in 1996 reported an 18% reduction in injury crashes. A 1997 study in the Netherlands reported a 25%–36% reduction in injury crashes (Oei et al., 1997). An evaluation of the Singapore red light camera program reported a 10% reduction in right-angle injury crashes, a 6% increase in rear-end injury crashes, and a 9% reduction in all injury crashes.

Research in the US state of California reported crash reductions of 7% following the introduction of red light cameras, with injury crashes reduced by 29%. Right-angle crashes at these intersections declined by 32% overall, and right-angle crashes involving injuries fell 68%. Rear-end crashes increased by 3%.

A study of six jurisdictions in the US state of Virginia reported an 8%–42% decline in red-light running crashes, but a 27%–42% increase in rear-end crashes. Whether or not the overall change in crashes was positive or negative depended on the crash distribution of the jurisdiction.

A 2005 study evaluated red light camera programs in seven US cities across three states. The study found that, overall, right-angle crashes decreased by 25% while rear-end collisions increased by 15%. The authors concluded that the economic costs from the increase in rear-end crashes were more than offset by the economic benefits from the decrease in right-angle crashes (Council et al., 2005).

A study compared large US cities that turned off red light cameras with those with continuous camera programs. In 14 cities that shut down their programs during 2010–14, the rate of fatal crashes at signalized intersections was 16% higher than would have been expected if they had left the cameras on. A study comparing large cities with red light cameras to those without found the devices reduced the rate of fatal crashes at signalized intersections by 14% (Hu and Cicchino, 2017).

A study in the US city of Houston, which had a red light camera program from 2008 to 2011, found that the camera activation was associated with a 47% decline in right-angle crashes and an 18% increase in rear-end crashes. Conversely, the deactivation was

associated with a 23% increase in right-angle crashes. However, rear-end crashes also went up by 14% after the cameras were deactivated.

A review of international red light camera studies concluded that cameras reduce injury crashes by 25%–30%. A second international review estimated a 13%–29% reduction in all types of injury crashes and a 24% reduction in right-angle injury crashes. A third review concluded that fatal crashes were reduced by 17% and injury crashes were reduced by 12%, but property-damage-only crashes were increased by 3%. Rear-end crashes were increased by 39% (Hoye, 2013).

The study of speed-on-green/red light cameras in Winnipeg reported a 46% reduction in right-angle crashes, an initial 42% increase in rear-end crashes followed by a 19% decrease, and no change in speeding-related crashes. A study in Belgium reported a 6% reduction in right-angle crashes, a 44% increase in rear-end crashes, and a 5% increase in all injury crashes.

Best Practices

Although photo enforcement has generally been successful in reducing the types of driver behavior and crashes that were targeted, there have sometimes been unintended consequences—for example, an increase in rear-end crashes. The same phenomenon has been observed when traffic signals are first added to intersections. Increasing the number of vehicle stops increases the chances for a rear-end crash. It is likely that the increase in rear-end crashes at photo enforcement sites is due to drivers braking suddenly and unexpectedly. Over time this behavior may decrease as drivers become accustomed to the changes. Even so, the overall benefit of a proposed traffic enforcement camera may depend on the historical distribution of crashes at the site. If rear-end crashes greatly outnumber crashes associated with speeding or red light running, then installing an enforcement camera may not be advisable.

The most successful photo enforcement programs have concentrated their efforts on sites with a significant speeding or red light violation problem that has not been solved by traditional enforcement or traffic engineering measures. Photo enforcement is a supplement to the traditional measures—not a replacement.

Another key aspect of successful programs is widespread exposure. Drivers will not change their behavior if they are not aware of the enforcement program. Extensive media coverage, warning signs near the camera sites, highly visible cameras, and published lists of enforcement sites have been used to increase driver awareness.

Citing the owner of the vehicle with the violation (similar to a parking citation) eliminates the need to photograph and identify the driver. This means less work for those reviewing the vehicle photographs while reducing complaints of invasion of privacy.

Importantly, public support is needed if a photo enforcement program is to be sustained. Communities employing automated enforcement must be careful not to give the impression that it is a moneymaking scheme. Counting on automated enforcement fines to balance the budget or redefining the criteria for a violation is a sure way to lose public support.

Basic Introduction to PTWs

What are PTWs?

The term "PTWs" refers to motorized two- or three-wheeled vehicles, powered by either a combustion engine or rechargeable batteries. These powered vehicles can be divided into different categories, including motorcycles (street, classic, performance or super-sport, touring, custom, off-road), scooters, electric bikes, and tricycles. A powered two-wheeler is any two-wheeled vehicle propelled by any type of power, in addition to pedaling, which is divided into ultra-light moped, moped, light motorcycle, and motorcycle (MC) according to the engine displacement, maximum speed and maximum weight. E-bikes are two-wheeled bicycles propelled by human pedaling but supplemented by electrical power from a storage battery, which can be divided into bicycle-style and scooter-style. A powered three-wheeler is a three-wheeled vehicle propelled by a motor, generally used for commercial transport of passengers. Most powered three-wheelers are motor-rickshaws (also referred to as e-rickshaws which run on electric batteries) (WHO, 2017).

Global Distribution of PTWs

There is a fast-growing number of PTWs around the world. According to the global status report on road safety 2015 of the World Health Organization, the fleet of global registered PTWs was around 516 million in 2013, compared to the figure of 313 million in 2008. It should be noted that non-motorized two- or three-wheelers (such as electric bicycles), which do not need to be registered were not included in these figures. In addition, given the absence of a registration system in many low- and middle-income countries, these figures tend to be further underestimated. Nevertheless, low- and middle-income countries still account for the vast majority (about 88%) of global PTWs (WHO, 2015).

According to the statistics from the World Health Organization, the largest proportion of registered PTWs (74.5%) was in South-East Asia Region in 2013 (WHO, 2015). Within South-East Asia, China was the largest motorcycle producer and saw an increase in the number of registered motorcycles by 21% during the period from 2007 to 2013, reaching 109 million (Traffic Management Bureau of the Ministry of Public Security, 2014). In Vietnam, motorized two- or three-wheelers accounted for 95% of all registered vehicles, with the rapid growth of approximately 7,500 newly registered motorcycles each day (WHO, 2013).

How PTWs are Used?

PTWs come in diverse forms and are used for different purposes in different parts of the world. In high-income countries (e.g., United States), high-powered motorcycles are commonly used by single riders for recreation, while in low- and middle-income countries, motorcycles with lower engine capacities often carry pillion passengers and are more commonly used for mobility or commercial purposes.

Traffic Safety Challenges With PTWs

Recent Trends in PTW Crashes

The rapid growth in the sales, registrations, and activities of PTWs around the world in recent years has led to more PTW crashes, injuries, and fatalities. In addition, the increase in the world population and the number of people who realize the potential benefits to the economy, mobility, and environmental sustainability of PTWs make the traffic safety associated with PTWs more challenging.

Compared with the occupants of other motorized vehicles, PTWs users lack nearly all protections offered to car occupants, which lead to their extrusive vulnerability to injury. After controlling for per vehicle mile traveled, motorcyclists are reported to suffer a 26-fold higher risk of death in a crash than those driving other types of motor vehicles (National Highway Traffic Safety Administration, 2015). As one of the most vulnerable road-user groups, PTW users represent 28% of all road deaths around the world while in South-East Asia, Africa, and the Western Pacific, they account for a larger proportion of deaths on roads, with the figures of 43%, 40%, and 36%, respectively (WHO, 2015).

Road User Characteristics Associated With PTW Crashes

Age

The age distribution of PTW users in crashes roughly follows the age distribution of PTW user population. In low- and middle-income countries, most PTW users are aged 15–34 years, and the majority of fatalities also fall into the same age group. While in high-income countries, PTWs are widely used by people aged 35 years or older, and the mean age for PTW users killed as a result of a crash is about 55 years (WHO, 2017).

Young and senior PTW riders have a higher injury risk in a crash, compared to middle-aged riders. The increased injury risk among young riders is predominantly associated with their lack of experience and tendency to exhibit risky behavior (Vlahogianni et al., 2012). In terms of older riders, the higher probability of being involved in fatal crashes is attributed to their decreased reaction ability, reduced sensory and perceptual ability, and less physical resiliency to crashes (Chang et al., 2019).

Gender

The association between rider gender and PTW crashes has been widely explored by researchers. Overall a much higher crash risk for men than for women has been reported per mile driven. This could be explained by the differences in type of travel, risk taking, natural fragility, choice of vehicle, travel purposes between men and women, etc. (WHO, 2017). In terms of injury risks, female motorcycle riders were found more likely to be involved in serious injuries (Savolainen and Mannering, 2007a).

PTW Users' Attitudes and Driving Behavior

Motorcycle riding is considered as dangerous activity and tend to attract risk-seeking individuals, especially young people. Young riders tend to make more "attitudinal" errors, which are directly associated with their risk-taking behavior such as speeding and alcohol consumption, while young riders' risk-taking behavior have been demonstrated to be major contributing factors to road traffic crashes and injuries. As such, much research focus on exploring young PTW drivers' attitudes toward traffic safety and the associated risk-taking behavior (Vlahogianni et al., 2012).

Personality traits including anxiety, anger, sensation-seeking, and normlessness are found to have direct effects on young motorcycle riders' attitudes toward traffic safety. More specifically, riders who tend to be angry, sensation-seeking, and normless have a higher likelihood of engaging in unsafe driving behavior (Wong et al., 2010). PTW riding attitudes are also greatly affected by socio-cultural factors and socio-economic factors (Li et al., 2009). The attempt to reveal factors related to casualty risks, such as speed, gender, age, and lack of concentration could be inefficient, if social and cultural factors are not taken into consideration.

Personality traits also have indirect impacts on riders' risk-taking behavior, mediated by traffic safety attitudes. Overconfident, sensation-seeking, amiable and impatient riders tend to behave unsafely. In addition, risk-taking behavior is associated with rider age and experience (Wong et al., 2010). Although a period of absence from riding might lead to a decline in safety-related motorcycle skills, the identified specific patterns of youth behavior play a much greater role in crash involvement than inexperience (Rutter and Quine, 1996).

Nonuse of Helmets

The protective effect of helmets on users involving in crashes has been well-documented (Kim et al., 2015). For example, the use of helmets can protect riders from suffering from neck and head injuries, which are two main causes of death, severe injury and disability for PTW users. During the crash occurrence, PTW users might collide with other objects or road surface, which could lead to different types of injuries. The use of helmets prevents riders' brain from direct contact with the road surface or other objects and thus reduces the risk of serious head and neck injuries by reducing the impact of force. However, non-standard helmet and incorrect use of helmet could weaken its protection given to riders. Therefore, the use of helmet, the proper way to use it, and helmet quality should be emphasized equally to maximize the protection for riders.

Lack of Conspicuity

Due to the smaller size and rapid acceleration, PTWs are often not perceived by other drivers in time to avoid a hazardous situation. Based on some research reports, most car drivers involved in crashes admit having looked in the direction of the PTWs prior to maneuvering, but failed to detect the approaching motorcycle (Pai et al., 2009). Riders' right-of-way is often violated by other motorists due to the conspicuity issues associated with motorcycles, leading to automobile-motorcycle gap-acceptance crashes, especially at priority (i.e., stop-/yield-controlled) T-intersections (Pai et al., 2009). Therefore, reflective or fluorescent clothing and headlight operation is suggested to address conspicuity issues and reduce the potential for crashes.

Road Environment Associated With PTW Crashes

Mixed Traffic

In many countries, PTW riders share the road with other motorized vehicles, which significantly increase the likelihood of crash occurrences. In low- and middle-income countries, where there is a large PTW fleet, the increases in the interactions between PTW users and motor vehicles lead to a higher-level crash risk. While in high-income countries, many other drivers are not familiar with PTWs and thus it's difficult for them to detect PTWs or judge PTWs' speed in mixed traffic. This unfamiliarity is likely to result in dangerous conditions for PTW users (Gershon et al., 2012).

Design of Road Infrastructure

The design of road infrastructure such as road geometry and road layout is an important predictor of crash occurrence and crash-related injury severity of PTW users (Manan, 2014). The impacts of horizontal curves on PTW crashes have been underlined. Motorcycle riders tend to be involved in out-of-control crashes on horizontal curves, which is mainly due to acceleration or deceleration, or instability on curves. Both the radius and the length of horizontal curves are significantly associated with the risk of single-vehicle motorcycle crashes. Although motorcycle crash risks are found to vary with travel purpose (commuting or recreational), this influence may be explained by various road environments associated with different traffic purposes, given that a higher proportion of crashes during the recreational period were found on curves while most crashes during the commuting period occurred on straight roadways and at junctions. In addition, curve type, horizontal and vertical sight distance, and turning provision, lane and shoulder width, and surface friction were demonstrated to be significantly associated with the severity of PTW crashes (Milling and Hillier, 2015).

Crash barriers have a strong impact on the injuries associated with PTW crashes. PTW users account for 42% of all deaths resulting from guardrail crashes in the United States, and 22% of the fatalities from concrete barrier crashes (Gabler, 2007). Among collisions with guardrails, the fatality rate of PTW riders is 80 times higher than that of other vehicle users. PTW users involved in fatal crashes are reported to collide with the barriers at a relatively shallow angle of 15–45 degrees (Gibson and Benetatos, 2000). The exposed posts of the barrier are generally the main cause of injury for the crash-involved PTW users (Gibson and Benetatos, 2000).

Junction Type

Junction type plays an important role in PTW crashes. In terms of crash risk, motorcyclists are over exposed at signalized intersections (Pai and Saleh, 2007). In addition, motorcyclists' injury severities tend to increase at junctions due to their susceptibility to crash injuries which act synergistically with the complexity of conflicting movements and maneuvers between motorcycles and automobiles. More than half of motorcycle crashes causing injuries were found at T-junctions, among which motorcycle-automobile angle crashes were identified as the most common crash type (Pai et al., 2009; Pai and Saleh, 2007).

Another type of location where motorcyclists are overrepresented in fatal crashes are modern roundabouts, at least in the United States (Steyn et al., 2015). A summary that was made on May 12, 2019, shows there has so far (1990–2019) been 81 fatal crashes at modern roundabouts in the United States, killing 89 people. One pedestrian and two bicyclist have been killed but at least 30 motorcyclists are victims. (A number of the victims are shown as unknown type but motorcycles make up over a third of all fatalities). At roundabouts, it is difficult to get killed in an automobile if you drive at the design speed, typically around 18–25 mph, and automobile occupants killed are frequently high-speed single vehicle crashes. But motorcyclists can get killed at low speed, and motorcyclists also sometimes enter roundabouts at speeds way above the intended speed losing control.

Factors that are deadly to motorcyclists vary with traffic control measures employed at junctions (Pai and Saleh, 2007). Male riders were found to be more injurious than females at stop, give-way signs, markings-controlled junctions, and signalized junctions. Elderly drivers, riding in early morning or on weekend, street lights unlit, and head-on collisions appear to predispose motorcyclists to more severe injuries at stop, give-way signs or markings-controlled and uncontrolled junctions. Despite different influential factors of crashes in junctions controlled by various measures, greater motorcycle engine size, good weather, non-built-up road, and collisions with bus/coach or heavy good vehicle (HGV) result in more severe injuries regardless of the employed control measures.

Pavement Surface Quality

PTWs are more sensitive to road surface condition than other motor vehicles. Pavement surface conditions are found to significantly impact sideswipe crashes between motorcycles and other motor vehicles at junctions and at-fault motorcycle crashes at non-junctions (Haque et al., 2009; Shankar and Mannering, 1996). Nevertheless, in certain circumstances, drivers' compensation behavior can mitigate the risks, for example, lowering speed on a wet pavement surface.

Surface grip, surface irregularities and potholes, loose materials, patch repairs, and road markings are suggested to be important contributing factors in crashes. Especially, motorcycles are very sensitive to changes in friction level between the pavement surface and tires (Pearson and Whittington, 2001); once the friction between a tire and the terrain is reduced, the centrifugal force and the weight force, which are centered in the center of gravity, create a momentum leading the motorcycle to a sudden rotation and instability (Cossalter et al., 2007).

Vehicle Characteristics Associated With PTWs Crashes

PTW type has an important influence on crash risks. In a study conducted in Queensland, Australia, the crash risk of mopeds appears higher than that of motorcycles and larger scooters; moped and scooter crashes are, on average, less severe than motorcycle crashes (Blackman and Haworth, 2013). In addition, the engine size of motorcycles has been widely demonstrated to be associated with crash severity. As motorcycles with larger engine capacity are always associated with larger vehicle mass, greater power and potential speed, increased motorcycle engine size tends to result in more serious injuries for motorcycle riders (Pai and Saleh, 2007).

Weather Conditions Associated With PTWs Crashes

It seems that PTW riding is more likely influenced by weather than other motor vehicle drivers, given that PTW users are exposed to the outside environment. However, weather has rarely been reported to be a contributing factor in motorcycle crashes. Moreover, weather made no contribution in 92.7% of crashes according to a European and Australian large-scale study (ACEM, 2003; Johnston et al., 2008). A larger number of severe PTW injuries appear to occur under fine weather (Pai and Saleh, 2007). This result can partly be explained by the fact that riding is mainly a recreation activity in many parts around the world and purely influenced by weather conditions. In other countries where PTWs primarily are used as a means of transportation in daily life, users are more likely to shift to other modes of transportation (e.g., car, public transport) under adverse weather conditions.

A Growing Traffic Safety Challenge With E-Bikes in China

Electric bikes—which provide an affordable, convenient, physical labor-saving, and energy-saving personal transportation mode—are becoming increasingly popular in many countries throughout Asia and Europe, especially in China. E-bikes were introduced into China in the late 1990s. Since, the introduction of legislation to deal with e-bikes, the number of e-bikes in China has skyrocketed from 40,000 in 1998 to about 250 million in 2018 (WHO, 2017). The tremendous growth and popularity of e-bikes entail traffic safety concerns among the public as observed in crash statistics. A total of 56,200 casualty crashes involving e-bikes during the period 2013–17 resulted in 8,431 fatalities, 63,500 injuries and about 16.5 million US dollars (Equivalent to 111 million RMB) of direct property damage in China (National Bureau of Statistics of China, 2018).

E-bikes are classified as nonmotorized vehicles according to traffic laws in China. Thus, no license, insurance, or helmet use is required for e-bike riders. E-bike riders who have a driver's license were found less likely to be involved in at-fault crashes than those without a license, which imply the lack of traffic knowledge or risk perception ability for e-bike riders. This conclusion could be further supported by the phenomenon that quite a large proportion of e-bike riders travel and behave illegally in motor vehicle lanes. The most common and potentially unsafe e-bike riding behavior include speeding, carrying passengers illegally, riding against the traffic flow, violating traffic signals, and using a mobile phone while riding (Du et al., 2014).

Interventions to Improve PTWs Traffic Safety

Safer Road Users

Addressing Road User's Illegal Behavior

The improvement of road user behavior is crucial in addressing road traffic safety issues. During a quite long period, counter-measures, including training and licensing, enforcement and communication campaigns, have been generally developed for drivers' better operations on roads.

Inexperience is a significant contributor to motorcycle crashes but the training and licensing system showed limited success in ensuring the safety of motorcycle riders (Haworth and Rowden, 2010). Although the hazardous perception time decreases as PTWs users' experiences increase, it remains unclear whether there is any reduction in crashes for formally trained riders compared to those who have not undertaken a formal training course (Haworth and Mulvihill, 2005). The insignificant beneficial effects of training may be explained the improper training course setting which only focuses on basic maneuvering skills rather than changes in attitudes toward safety traffic situations or the ability to avoid emergency situations. What's more, a higher crash rate was even found for trained riders, which was attributed to the overconfidence caused by the training (Savolainen and Mannering, 2007b). The training course for motorcycle riders therefore needs to be improved for their safety traveling on roads. For more information about training, (Refer to the article 10128, Education and Training of Drivers).

Enforcement rather than education is believed to be more helpful in curbing motorized vehicle users' illegal behavior (Williams and Wells, 2004). Especially, stronger enforcement is needed to improve road users' compliance with safety rules against risky behavior such as speeding, drinking and driving, helmet use, and vehicle standards. In addition, highly visible enforcement activities should be developed sustainably to deter potential offenders.

As a common countermeasure, communication campaigns targeting specific groups or specific behavior have been demonstrated to be effective and used to promote traffic safety in many countries.

Promoting the Use of Personal Protective Equipment

The use of protective equipment such as helmet, and reflective and protective clothing is beneficial in preventing or reducing injuries of PTW users. Although wearing properly a quality-standard motorcycle helmet can reduce the risk of death by over 40% and the risk of severe injury by almost 70%, only 49 countries in the world have helmet laws that meet the best practice according to the following criteria used by WHO (WHO, 2018).

- Law mandates that helmets must be worn by all riders (drivers and passengers), on all roads and with all engine types.
- In addition, the law must specify that the helmet needs to be properly fastened.
- Law refers to a standard for helmets.

In order to reduce rider injury severity, every country should try to improve their helmet laws according to these criteria and make sure the law is strictly enforced.

Reflective and protective clothing such as jackets, pants, boots, and gloves is a promising intervention for reducing PTW injuries. By increasing the brightness, reflective clothing helps improve the visibility of PTW users and differentiate riders and passengers from surroundings. Protective clothing is specially designed to prevent, or reduce the injury severity when a crash occurs by providing adequate abrasion resistance and impact protection for users. Riders who wear a range of protective clothing are significantly less likely to be hospitalized (30%–60%) and less likely to incur injuries in crashes (de Rome et al., 2011). Despite its effectiveness, the use of protective clothing is rather limited, especially in low- and middle-income countries. Promoting and enforcing compliance is key to the successful implementation of this intervention.

Safer Roads

Road Design

As described in section Road Environment Associated with PTW Crashes, PTW users have a higher crash risk on curves, bends, slippery roads, and at junctions. Road surface and road-marking materials that provide better grip to PTWs are encouraged to ensure the stability of vehicles on roads (WHO, 2017). The radius and length of each horizontal curve should be appropriate and not require special riding skills of PTW users. Wider lanes on major and minor roads, and an increase in the number of lanes on major roads are also beneficial in reducing motorcycle crashes (Harmen et al., 2004). In terms of the higher crash risk at roundabouts, exclusive or protected (right hand) turn lanes and paved shoulders whose width is more than 1 meter may help to reduce motorcycle crashes at roundabouts. In addition, good visibility and signage around junctions and roundabouts also helps motorcyclists manage their speeds as they approach the sites. Due to the smaller size of motorcycles, signage, vegetation, other vehicle, and objects could obscure them, which should be taken into specific consideration when designing intersections and roundabouts.

Exclusive Motorcycles Lanes

Exclusive motorcycle lanes have been demonstrated effective in significantly reducing motorcycle crash frequency and severity by separating motorcycles from general traffic, especially from high-speed and heavier vehicles (Radin et al., 2000). However, setting

aside specific lanes for motorcycles is not generally economic and feasible in most countries. Segregation is likely to be significantly beneficial and acceptable to the public when the proportion of PTW users is more than 20%–30% of all vehicles on the road—as is the case in many low- and middle-income countries (Radin et al., 2000).

Speed Limits and Traffic Calming

Traffic calming measures are useful in reducing crashes for all vehicle types. But occasionally, such interventions, for example placing obstacles, including speed humps, and small vertical objects designed to minimize speed, might pose a negative effect on the safety of motorcycle riders (ITF, 2015). Other forms of traffic calming such as horizontal markings on the road used to warn motorcyclists of these obstacles are suggested. In addition, the choice of locations of traffic calming measures aiming at other vehicles should take into consideration the characteristics of PTW traffic.

Management of Roadside Hazards

PTW riders have an extremely high fatality risk, if colliding with a roadside obstacle (Daniello and Gabler, 2011). Eliminating roadside installations such as barriers, posts, utility poles, etc., can reduce the risk of a PTW rider impacting any hazardous objects as well as provide road users room to correct operation errors. Guardrails and crash barriers are often used to separate vehicles from roadside hazards but there is no consistent view about the best guardrail or crash barriers for motorcyclists. Increasing evidence showed that the position of motorcyclists impacting a guardrail may be more important than the type of guardrail. Motorcycle-friendly barriers that allow fallen motorcyclists to slide along the surface without impacting any specific component of the system are thus encouraged. In addition, it was also evidenced that collisions with fixed objects tend to result in more severe injuries to PTW users than collision with crash barriers, which support the use of barriers to prevent impacts with such objects (Bambach et al., 2013). Especially, the priority should be given to improving barriers and guardrails on curves, the proper placement and maintenance of guardrail and crash barrier systems.

In Sweden, where they have installed centerline cable barriers along over 1300 km of two-lane rural highways, motorcycle organizations were very skeptical about them, stating that the cable would act as a deadly object, if hit. However, evaluations have shown that these roads are safer for all road-users, even for MC riders, than undivided two-lane roads. A 2006 evaluation by the Swedish National Road and Transport Research Institute (VTI) shows that there would have been expected to be 67 motorcyclists killed or seriously injured in 2003–05 had the roads not had center barriers whereas the outcome was that only 22 motorcyclists were killed or seriously injured on these roads. So, the conclusion is that the benefit of not facing oncoming traffic very much outweighs the risk of injury from MC crashes involving the cable barrier (VTI, 2007).

Safer Vehicles

Antilock brake systems (ABS) and the use of headlights are two interventions demonstrated useful in improving PTWs traffic safety.

Antilock Brake Systems

Antilock brake systems have the potential to reduce the occurrence of PTW crashes and to mitigate their consequences by optimizing braking distance and helping riders sustain stability in emergency braking situations. By using ABS, the fatality rate of motorcycles could be reduced by 37%, and half of severe and fatal crashes among motorcycles over 125 cc could be avoided (Teoh, 2011). In 2016, the legislation for mandatory ABS equipment on all motorcycles (over 125 cc) was passed in the European Union. To improve the global motorcycle traffic safety, a similar law applicable for other regions is also needed.

Headlight On

The lack of conspicuity is one important factor contributing to PTW crashes. Mandatory use of headlights at daytime and night has been proven effective in increasing the conspicuity of PTWs and improving PTW safety (Radin et al., 1996). At nighttime, the use of headlamps can maximize visibility of—and the field of vision for—PTW riders, which lead to improved judgment accuracy of PTWs' approach-speed and the subsequent improvement of traffic safety. Driving with headlights on during daytime could reduce visibility-related crashes by between 29% and 40% (Radin et al., 1996). However, compliance with daytime running light legislation is impeded by various factors (e.g., energy savings) as well as by personal choice. Manufacturers play a critical role in promoting the use of daytime running lights, for example, equipping with Automatic Headlamp On at manufacturing stage to ensure the headlight is always on when the PTWs engine is running.

Interventions Related to E-Bikes

In order to improve e-bike traffic safety, a safety technical specification for electric bicycle was made inaction in 2018 and carried out from 15 April 2019 in China (Ministry of Industry and Information Technology of the People's Republic of China, 2018). The specification illustrates the standard of electric bicycles. In order to ensure the specification is implemented, State Administration for Market Regulation, Ministry of Industry and Information Technology of the People's Republic of China, the Ministry of Public Security of the People's Republic of China jointly issued the "Opinions on Strengthening the Implementation of National Standards for Electric Bicycles" which involves strict management of e-bike production, strict supervision of e-bike sales, strict registration and use management of e-bikes, dealing with the existing e-bikes that do not meet the new standard, establishment of a long-term

regulatory mechanism, and social publicity and guidance with the purpose of further standardizing the production, sales and use management of electric bicycles. The strict registration and use management of e-bikes will improve the efficiency of curbing of riders' traffic illegal behavior. Wearing a helmet when riding an electric bicycle is also suggested by these three national departments.

Introduction

Railroads play a vital role in transporting cargo and passengers in most countries around the world, and thereby contribute to the economy. In the United States (US), freight rail remains a crucial contributor to the movement of goods and passengers, while commuter ridership has also started to grow in recent years, balancing the nation's transportation options (FRA, 2016). The US freight rail network consists of close to 600 freight railroads, nearly 225,000 km (140,000 miles) of track with 2.8 trillion ton-km (1.74 trillion ton-miles) of traffic annually (AAR, 2018). Fig. 1 shows the current US freight network and passenger network for the United States and part of Canada. The 225,000 km in the United States equals 0.7 km per 1000 people, which is relatively typical from an international perspective. However, Africa and much of Asia have fewer miles of rail per capita. Worldwide, there were around 1,370,782 km of track in 2018. That is around 0.18 km of track per 1000 people. Conversely, most European countries have more tracks per capita. For example, Sweden has 14,475 km of active track, which equals 1.5 km per 1000 people. Also, the United States has only 1,600 km of electrified track, whereas Sweden has almost 9000 km, which is about 180 times more per capita. However, US railroads transport a lot of freight over long distances. The 2.8 trillion ton-km for the United States equals 8600 ton-km per capita. That can be compared to Swedish railroads carrying only 2,200 ton-km per capita.

The rail network of Amtrak (the National Railroad Passenger Corporation) consists of more than 34,000 route-km (FRA, 2019) and serves more than 500 destinations in 46 states plus the District of Columbia. In total, 28 commuter railroads provided over 499 million trips for passengers in 2018 in the United States (APTA, 2019). That equals roughly 1.5 trips per person per year, which is relatively low in an international comparison. For example, in Sweden, railroads carry around 230 million people per year, which equals 23 trips per capita, 15 times more than in the United States. In the United States, passenger rail carries around 10.3 billion passenger-km or 32 km per capita per year. Swedish railroads in 2016 carried people 1280 km per capita, 40 times as much as US railroads. The European Union (EU) uses a railroad network of over 130,000 miles. More specifically, Germany has the longest railway lines in the EU, with around 23,400 miles. The United Kingdom and Sweden have approximately 10,100 miles and 6800 miles, respectively (UNECE, 2019). In Asia, China and Japan have around 81,400 miles and 17,000 miles, respectively (World Bank, 2019). In these vast railroad networks, safety is of the utmost importance, since a train accident may result in numerous injuries or fatalities, substantial infrastructure and rolling stock damages, and severe environmental impacts. This chapter focuses primarily on railroad safety statistics, accident causes, and risk mitigation strategies in the United States. Some rail safety statistics are also given for the European Union (EU) and Japan.

Figure 2 Rail accident and injury rates (AAR, 2018).

Railroad Safety Statistics in the United States

The Association of American Railroads (AAR) point out that nothing is more important to railroads than safety. Railroads today have lower employee injury rates than most other major industries, including trucking, airlines, agriculture, mining, manufacturing, and construction—even lower than food stores (AAR, 2018). For the rail sector, rail safety data in many countries continue to show that recent years have been the safest on record. Fig. 2 presents trends in US railroad-related injuries and accidents over several decades, namely:

- The train accident rate in 2017 was down 79% from 1980 and down 41% from 2000;
- The employee injury rate in 2017 was down 83% from 1980 and down 43% from 2000.

Over the last ten years, the declining trend in US accident rates has slowed, though railroads continue to promote rail safety. According to recent FRA data, the train accident rate, defined as the number of accidents per million train miles, has been reduced by 10% and the employee injury rate is down 16% since 2009 and was around 1.4 accidents per million train km (2.3 per million train miles) in 2017 (AAR, 2019). Fig. 3 shows the accident rate from 2007 to 2017 for all railroads and all types of track combined. Since 2012, accident rates have fluctuated and insignificant decreases indicate the never-ending challenge railroad safety presents. Thus, railroads, in cooperation with policymakers, their employees, suppliers, and customers, are constantly looking for new technologies, operational enhancements, improved training, and other ways to further improve their already excellent safety records.

Figure 3 FRA-reportable accident rate for all railroads in the United States.

- Data source: FRA Rail Equipment Accident Database, 6180.54.
- “Accident” is the FRA-reportable accident in which reportable on-track equipment and track damage exceeds the monetary threshold for train accidents. The reporting threshold updates annually (e.g., \$7700 in 2007, \$9200 in 2010, or \$10,700 in 2017).
- “Other” includes highway-rail grade crossing accidents, obstruction, fire/violent rupture, etc.

Derailment and collision are the two major types of train accidents in the United States, accounting for over 75% of all types of accidents. Derailment, according to the FRA guide’s definition (FRA, 2011), is an accident that occurs when on-track equipment leaves the rail for a reason other than collision, explosion, highway-rail grade crossing impact, etc. A collision is defined as “an impact between on-track equipment consists while both are on rails and where one of the consists is operating under train movement rules or is subject to the protection afforded to trains.” This definition includes instances where a portion of a consist occupying a siding is fouling the mainline and is struck by an approaching train. Per the FRA Rail Equipment Accident (REA) database, 29,252 derailments and 4,000 collisions occurred in the United States from 2000 to 2017, leading to over \$4104 million and \$738 million in damage costs to infrastructure and rolling stock, respectively. On average, derailments in one year resulted in around 3 fatalities, 157 injuries, and \$228 million in damage costs. For collisions, the average annual consequence involves about 7 fatalities, 109 injuries, and \$41 million in damage costs. Since grade crossing accidents involve different accident characteristics, this article focuses on derailments and collisions, to the exclusion of grade crossing accidents, covered in a different article of this encyclopedia.

Railroad Safety Statistics in the EU and Japan

This section reviews some railroad safety statistics in the EU and Japan, with emphasis on fatalities due to train accidents. The main reason for this emphasis is that fatal accidents are mostly well-recorded, while nonfatal accidents are likely to be underreported or recorded and reported in diverse ways.

Table 1 shows traffic volumes measured in train-miles per year, fatality rates by person type, and estimated trends in fatal accident rates for the United States and European Union. In general, the EU has about three times as many fatalities of railroad passengers per billion train-miles as US railroads. The fatality rate is defined as the number of fatalities per billion train-miles and is calculated with two person types, which are railroad passengers and staff. If we instead use passenger-miles traveled as exposure, which is a more relevant measure, the result is reversed. Using 2018 passenger-miles traveled by train, the United States had 6.36 billion miles of

Table 1 Fatal railroad accident statistics in the EU and US (Evans, 2010, 2013)

	United States	European Union
Period covered	2000–09	2006–009
Billion train-miles per year	0.7497	2.5784
Fatalities per billion train-miles by person type		
Railroad passengers	9.3	27.2
Staff	35.4	13.8
Period covered	2000–17	1990–2009
Estimated rate of change in fatal accidents per billion train-miles	–7.2%	–6.3%

travel by Intercity trains and the EU had 293 billion miles (472 billion km) of travel that year, meaning the EU sees about 46 times as many miles of travel as the United States, and instead of having a risk per mile three times that of the United States, the risk per mile traveled is only 6% of that of traveling by train in the United States. This can also be expressed as the United States having a 15 times higher fatality risk per mile of travel. Another interesting safety-related statistic is that staff fatalities in the United States account for around 80% of all fatalities (covering both railroad passenger and staff, excluding trespassers) and the fatality rate is about two-and-a-half times that in the EU. The fact that the US railroad passenger fatality rate per train mile is smaller than in the EU is because US railroad operations mainly consist of freight trains, while Europe has a lot of passenger trains. Among EU countries, Sweden has the lowest fatality rate (Evans, 2013). At the end of 2009, Sweden had suffered no fatal train accidents since 1990. Since then, through October 2019, only one person has been killed onboard a train in Sweden as a result of an accident. That was on September 12, 2010, when a 24-year old woman was killed when a passenger train collided with an excavator. Furthermore, the estimated rate of change in fatal accident rates for 2000–17 US railroads and 1990–2009 EU railroads declined by 7.2% and 6.3%, respectively. Similarly, Japan also had around a 6.5% annual decline in the fatal train accident rate from 1971 to 2006 (Evans, 2010).

Railroad Accident Causes

Train accidents cause damage to infrastructure and rolling stock, as well as service disruptions, and may cause casualties and harm to the environment. Although train accidents occur as a result of many different causes, some are much more prevalent than others. Furthermore, the frequency and severity of accidents also vary widely, depending on the particular accident cause. The efficient allocation of resources to prevent accidents in the most cost-effective manner possible requires understanding which factors account for the greatest risks, and under what circumstances. Assessment of the benefits and costs of strategies to mitigate each accident cause can then be evaluated and resources can be allocated so that the greatest safety improvement can be achieved for the level of investment available. This section focuses on two major types of accident, train derailments and train collisions, which are among the most common types of accident.

Derailment

Train derailments are most common in countries with neglected track maintenance. However, derailment occurs in all countries. One of the most serious derailments in recent years occurred in Lac Megantic in Quebec, Canada in 2013. An unattended 74-car freight train carrying crude oil rolled down a 1.2% grade and derailed downtown, resulting in the fire and explosion of multiple tank cars. Forty-two people were confirmed dead and another five were missing and presumed dead. More than 30 buildings in the town's center, roughly half of the downtown area, were destroyed, and all but three of the thirty-nine remaining downtown buildings had to be demolished.

Another much publicized derailment occurred in Germany in 1998, near Eschede, when a high-speed train derailed and crashed into a road bridge, killing 101 people and injuring around 100 others on board. It remains the worst high-speed rail disaster worldwide. High-speed trains typically operate on well-maintained tracks, and Japan has operated Shinkansen trains for over 50 years, carrying over 10 billion passengers, and there have been no passenger fatalities due to train accidents such as derailments or collisions, despite frequent earthquakes and typhoons. France has been almost as successful with their high-speed TGV trains: they had a derailment when testing a train, but have not had a single fatality from derailments or collisions during operations with passengers. The service started in 1981 and TGV trains have transported 1.2 billion passengers and now transport 50 billion passenger-kilometers per year on *lignes à grande vitesse* (high-speed lines) alone.

Below, we will look more in depth at derailments on US railroads.

For the period from 2001 to 2010, 8092 train derailments occurred on Class I freight railroads, which account for approximately 68% of US railroad route miles, 97% of total ton-miles transported, and 94% of the total rail freight revenue (AAR, 2018). The seven Class I freight railroads that operate in the United States are Burlington Northern Santa Fe Railway (BNSF), CSX Transportation (CSX), Grand Trunk Corporation (CN), Kansas City Southern Railway (KCS), Norfolk Southern Combined Railroad Subsidiaries (NS), Soo Line Corporation (CP), and Union Pacific Railroad (UP).

Four types of tracks are recorded in the FRA Rail Equipment Accident (REA) database: main, siding, yard, and industry tracks. These track types are used for different operational functions and consequently have different associated accident types, causes, and consequences. Main, siding, yard, and industry account for 54.9%, 35.2%, 5.4%, and 4.7% of all freight train derailments from 2001 to 2010, respectively (Table 2). Of the four track types, freight train derailments that occurred on main lines had the greatest frequency and severity (measured in average number of cars derailed per accident). For the period 2001–2010, 4439 train derailments occurred in Class I freight railroads. These accidents led to 37,456 total cars derailed, or equivalently, one Class I freight railroad derailment resulted in an average of over 8 derailed cars per accident from 2001 to 2010.

The primary causes of derailments on Class I mainlines are divided into 49 categories or causal groups. Table 3 presents the top 10 derailment cause groups for main, siding, and yard, according to accident data from the Federal Railroad Administration. Broken rails or welds act as the most common cause for all three track types and contributed to around 16% of freight train derailments for all three track types from 2001 to 2010. In particular, broken rails and welds on main lines were more than twice as likely to have been the cause of train derailments than the second and third leading causes (track geometry and bearing failure). Broken rails or welds make up one track-related accident cause group, which includes but is not limited to transverse defect, detail fracture, broken

Table 2 Derailment frequency and severity by track type, US Class I Freight Railroads, 2001–10 (Liu et al., 2012)

Track type	Main	Yard	Siding	Industry	All
Number of freight train accidents (frequency)	4439	2848	436	369	8092
Average number of cars derailed per accident (severity)	8.4	4.7	5.7	4.3	6.8
Total number of cars derailed	37,456	13,363	2477	1593	54,889

Per the FRA guide's definitions of tracks:

- Main track: a track extending through yards or between stations, upon which trains are operated by timetable or train order or both, or the use of which is governed by a signal system.
- Yard track: a system of tracks within defined limits used for the making up or breaking up of trains, for the storage of cars, and for other purposes over which movements not authorized by timetable or by train order may be made.
- Siding: a track auxiliary to the main track used for meeting or passing trains.
- Industry track: a switching track, or series of tracks, serving the needs of a commercial industry other than a railroad.

Table 3 Top 10 accident causes of US freight train derailments by track type, 2001–10 (Liu et al., 2012)

Freight Train Derailments						
Main			Siding		Yard	
Rank	Cause group	Percentage	Cause group	Percentage	Cause group	Percentage
1	Broken rails or welds	15.3	Broken rails or welds	16.5	Broken rails or welds	16.4
2	Track geometry (excluding wide gauge)	7.3	Wide gauge	14.2	Use of switches	13.5
3	Bearing failure (car)	5.9	Turnout defects—switches	9.7	Wide gauge	13.5
4	Broken wheels (car)	5.2	Switching rules	7.7	Turnout defects—switches	11.1
5	Train handling (excluding brakes)	4.6	Track geometry (excluding wide gauge)	7.2	Train handling (excluding brakes)	6.7
6	Wide gauge	3.9	Use of switches	5.8	Switching rules	6.2
7	Obstructions	3.5	Train handling (excluding brakes)	3.5	Track geometry (excluding wide gauge)	3.6
8	Buckled track	3.4	Lading problems	2.3	Miscellaneous track and structure defects	3.4
9	Track-train interaction	3.4	Roadbed defects	2.1	Track-train interaction	3.1
10	Other axle or journal defects (car)	3.3	Miscellaneous track and structure defects	2.1	Other miscellaneous	3.0

rails at base or weld, fractures from shelling or head checks, etc. (Fig. 4). Track geometry is the second major cause of mainline derailments, while wide gauge and use of switches are the second most frequent causes in siding and yard.

Fig. 5 plots derailment frequency and severity, defined as the average number of cars derailed, with frequency on the abscissa (x -axis) and severity on the ordinate (y -axis). Of the four quadrants defined on the basis of the average derailment frequency and severity along each axis, the causes in the upper right quadrant are most likely to pose the greatest risk because they are both more frequent and more severe on average. There are five causation groups in the upper right quadrant: broken rails or welds, wide gauge, buckled track, obstructions, and mainline brake operation.

In addition, there are four other causation groups that have a notably high frequency of occurrence: track geometry (excluding wide gauge), bearing failure (car), broken wheels (car), and train handling (excluding brakes). Three other causation groups are notable because of the high average severity of the resultant derailments: rail defects at bolted joints, other rail and joint defects, and joint bar defects. These last three causes, along with the related causation group of broken rails or welds, are of particular interest, because together they account for almost 20% of all derailments and more than 30% of all derailed cars on Class I main lines.

Fig. 6 presents the primary causes for freight train derailments on Class I mainlines by the number of cars derailed. Broken rails or welds are by far the most common, accounting for 23% of total cars derailed from 2001 to 2010. Causal groups 2 through 10 account for 39%. In other words, the top 10 causal categories are responsible for 62% of cars derailed. Combined, the other 39 identified causal groups account for the remaining 38%. Since broken rails are responsible for the most derailments and cars derailed, focusing on their prevention is likely a promising risk-reduction strategy.

Figure 4 Examples of two common types of broken rail. (A) Transverse defect; (B) Detail fracture. Source: Federal Railroad Administration, 2015. *Track Inspector Rail Defect Reference Manual*; TRAINS Magazine, 2017. *Broken Rails: An Unexpected Pain*.

Figure 5 Derailment frequency and severity by accident cause on class I mainline, sorted by frequency (Liu et al., 2012).

Collision

Below, we will look in depth at US train collisions in recent years.

From 2001 to 2015, 394 freight train collisions occurred in the United States. Each collision led to an average of over one casualty per accident and \$0.67 million of monetary damage costs to infrastructure and rolling stock. There are 16 causes (related to human factors, signals, or miscellaneous cause groups) associated with collisions on US mainlines. This frequency analysis shows that the failure to obey or display signals, violation of train speed rules, and violation of mainline operating rules are the top three collision causes from 2001 to 2015 (Fig. 7).

Collisions caused by failures to obey or display signals resulted in an average of around 2 casualties, including both fatalities and injuries, and around \$1.23 million of monetary damage costs to infrastructure and rolling stock. The cause group designated as the failure to obey or display signals includes but is not limited to the following cases:

Figure 6 Primary causes for 2001–10 freight train derailments on class I mainlines by number of cars derailed. Source: Rutgers Center for Advanced Infrastructure and Transportation, 2019. RU Rail Expert's Research Chosen for Special Issue of "Transportation Research Record".

Figure 7 Number of collisions by cause, U.S. Mainlines, 2001–15 (Turla et al., 2018). H, Human factors in train operations; M, Miscellaneous causes; S, Signal and communication.

- Failure to observe hand signals given during a wayside inspection of a moving train;
- Failure to comply with failed equipment detector warnings or with applicable train inspection rules;
- Improperly displayed fixed signals (other than automatic block or interlocking signals);
- Failure to comply with fixed signals (other than automatic block or interlocking signals);
- Failure to comply with automatic block or interlocking signals;
- Absence of blue signals;
- Improper use of flagging;
- Failure to comply with flagging;
- Failure to comply with hand signals;
- Improper use of hand signals;
- Failure to give or receive hand signals.

Figure 8 Collision severity by major cause, U.S. Mainlines (Turla et al., 2018).

The second most frequent collision cause group, violation of train speed rules, includes excessive coupling speed, failure to comply with restricted speeds in connection with the restrictive indication of a block or interlocking signal, trains moving at excessive speeds, and switching movement with excessive speeds. The cause group designated as the violation of mainline rules covers failure to stop the train, and failure to comply with motor car or on-track equipment rules, train orders, track warrants, track bulletins, timetable authority, etc. For the comprehensive definition of the miscellaneous cause group in freight-train collisions, refer to [ADL \(1996\)](#) and [FRA \(2011\)](#). In addition to the number of collisions by cause, the average severity in terms of injuries, fatalities, and damage costs per collision due to each cause group is also presented in [Fig. 8](#). Failure to obey/display signals, as the most frequent collision cause group, also has the highest number of injuries per collision and the greatest damage costs per collision.

Risk Mitigation Strategies

While rail safety remains at an all-time high, continuous efforts are essential to protect the public and rail workers. Continuous safety improvement requires comprehensive strategies designed to eliminate risks on railroads. The Federal Railroad Administration of the US Department of Transportation and railroad companies are collaborating to increase safety via three major domains: track, mechanical, and human factors. Safety improvements are ensured by merging proven safety approaches with performance-based measures that improve the culture around safety and harness technology and research.

Track-Related Risk Prevention

Rail Inspection

Rail inspection is the activity of examining railroad safety and serviceability, as one critical aspect of the operation of a rail network. A variety of nondestructive testing (NDT) technologies have been employed or developed ([Fig. 9](#)). For example, ultrasonic waves are employed to detect surface defects, internal railhead defects, and rail web and base defects. However, they can sometimes miss rail foot defects and can also miss internal defects and surface defects that are smaller than 4 mm at high speeds (e.g., greater than 70 km/h) ([Cheng and Bond, 2015](#)). In the detection of internal defects, radiography, laser ultrasonics, and electromagnetic acoustic transducers are three feasible technologies that overcome the limitations of most other means, although they can be adversely affected by lift-off variations.

FRA rail inspection car. <http://photos.nerail.org/?p=245203>.

Track Geometry Measurement and Analytics

The inherent and small geometrical deviations in the position of rails from their ideal design states constitute imperfections that can have a significant impact on the safety and the rate of degradation of the rail system. Causal analysis discloses that track geometry is the second most frequent FRA-reportable derailment cause on Class I freight railroad mainlines. Track geometry measurement technologies and assessment using various statistical techniques contribute to rail track safety and maintenance decisions. Main track geometry defects include alignment, profile, gauge, cant, and twist defects.

The Autonomous Track Geometry Measurement Systems (ATGMS) technology is employed to improve rail safety by increasing the availability of track geometry data (Fig. 10). Routine use of ATGMS technology by the rail industry will eventually lead to minimized interference of inspections to revenue operations, increased inspection frequencies, and the reduced lifecycle cost of

Figure 10 Autonomous track geometry measurement system technology (ProgressiveRailroading.com/railproducts, 2016).

inspection operations, all of which will lead to improved safety and maintenance planning. There are three major components in ATGMS: onboard units, wireless communication links, and processing servers ([Carr et al., 2009](#)).

- Onboard units consist of a series of sensors, a computing platform, and location determination technology, such as Global Positioning System (GPS) technologies.
- Processing servers feature data processing capabilities, a database management system, and Geographic Information Systems (GIS) applications to facilitate the reporting of areas of interest. The server-based software performs a series of quality checks to ensure the continuity of data and subsequently converts sensor data into foot-by-foot geometry measurements.
- Communication links, constituting an important feature of any autonomous inspection system, are the manner in which data is transferred between the onboard units, the central processing servers, and the data recipients. They affect the way in which measured data is uploaded to the central processing servers, and processed information is distributed to inspectors or maintenance personnel.

The implementation of ATGMS can improve rail safety by increasing the availability of track geometry data for safety and maintenance planning purposes. The key feature of this technology is that it is a relatively low-cost, self-powered geometry measurement system for a wide range of rail vehicles, especially for freight trains.

Moreover, additional technologies and approaches have also been employed in the United States. [Andani et al. \(2015\)](#) investigated a light detection and ranging (LIDAR) sensor for the collection of horizontal alignment data, and their test, carried out on a revenue service track, indicated that LIDAR optics can provide a reliable track monitoring instrument with a wavelength range of 9.45–18.9 m for use over substantial track mileage in inclement weather and harsh track conditions with minimal operator supervision. Furthermore, the BNSF Railway has utilized unmanned aerial vehicles (UAV) to monitor track quality while safety experts monitored the drones' video feeds to precisely view rail tracks.

To characterize and predict track geometry component degradation over time, track geometry can be modeled in statistical forms. The Track Quality Index (TQI) was developed for the evaluation of the quality indicators of track geometry, in order to determine which are most conducive to accurately describing and predicting track geometry. One methodology is to employ multiple regressions to varying parameters, such as vertical and horizontal alignments, gauge, cant and twist qualities, and then filter wavelengths across curved and straight tracks. The standard deviation of the vertical alignment with a wavelength between 3 and 25 m was found to be a good parameter to describe the influence of track geometry on vehicle behavior ([Haigermoser et al., 2014](#)). In addition to the use of a TQI, Markov-based models ([Bai et al., 2015](#)), neural networks ([Sadeghi and Askarinejad, 2012](#)), and probabilistic stochastic approaches ([Andrade and Teixeira, 2011](#)) have all been employed in the study of track geometry.

Improved Materials and Manufacturing

Over the last few decades, the quality of steel manufacturing has kept improving, eliminating many fatigue failures due to internal defects. Internal defects are generally caused by inherent flaws in the rail that form when the rail is manufactured. Thus, advances in rail manufacturing can prevent the occurrence of internal defects that are nearly impossible to detect at early stages. [Smith \(2005\)](#) stated that the greatest improvement to steel manufacture in the last 30 years has been the use of welding to eliminate fish-plated gaps in the running surface, which is probably the most significant development since the introduction of the steel rail. Rail is now manufactured in strings up to 250 m long, simplifying the laying of track and reducing the number of welds. Although welds are one potential source of weakness, the thermit welding process, used in the field to join long rail strings, is continuously being improved as well. Furthermore, with the development of high-speed railways in some areas, aerospace technologies are increasingly being adapted in terms of materials (e.g., aluminums and composites), manufacturing methods, and inspection techniques ([Smith, 2005](#)).

Mechanical-Related Strategies

Manual Inspection

The Federal Railroad Administration (FRA) of the US Department of Transportation requires that every car placed in the train must receive a mechanical inspection before the train departs from a yard or terminal. In addition, trains traveling long distances must stop for inspection every 1000 miles, with an exception under special conditions that allows travel up to 3500 miles.

Traditional railcar inspection practices require a car inspector, referred to as a carman, to walk or take a vehicle along the entire length of a train, visually inspecting the mechanical components on each car ([Schlake et al., 2010](#)) ([Fig. 11](#)). In most cases, two carmen are assigned to each train so that one can inspect each side of the train. Although there is slight variance by railroad and location, the common procedures for Class I railroad inspection performed by car inspectors remain relatively consistent and can be divided into several distinct steps: (1) secure track protection, (2) inspect train, (3) make necessary minor repairs and/or identify bad-order cars, (4) perform air test, (5) release brakes, (6) verify brake release, (7) remove track protection.

Depending on the carmen's training, experience, and working conditions, these inspections can be inconsistent in their objectivity and effectiveness. As a result, a train may be inspected to the best of a particular carman's ability, yet defects may be missed ([Schlake et al., 2010](#)). There are a variety of safe, efficient, and traceable means of rolling stock inspection that automate the mechanical inspection process by employing multiple technologies. These technologies include but are not limited to: wheel impact load detectors (WILDs); truck performance detectors (TPDs); acoustic bearing detectors (ABDs); and machine vision inspection of

Figure 11 Train inspections with carmen (Schlake, 2011).

Figure 12 Architecture of measurement equipment (Schlake et al., 2010).

truck components, safety appliances, and brake shoes. The machine vision-based railcar inspection and acoustic bearing detectors are introduced below as two examples.

Machine Vision-Based Inspection

The inspection of railcar underframe components using machine vision technology is used to automate critical inspection tasks with high efficiency and effectiveness. A digital video system was developed to record images of railcar underframes, along with computer software to identify components and assess their condition. Railcar structural underframe components include the center sill, side sills, and crossbearers, which are subject to fatigue cracking due to periodic and/or cyclic loading during service and other forms of damage. Tests of the image recording system were conducted at Norfolk Southern (NS) maintenance facility in Decatur, Illinois, with two cameras (Fig. 12).

With the help of multi-scale image segmentation, pixel neighborhoods of varying size can be accessed and used for the detection and inspection of defects and cracks in structural underframe components. A crack can be modeled as a homogeneous, elongated region that appears darker than the center sill. Similarly, a break can be modeled as a dark region that represents a discontinuity in the following properties of the center sill: brightness, contiguity of the sill's contours, and co-linearity and parallelism with parts of the center sill's contours. For example, to detect a cracked center sill, the technology can identify the region that delineates the boundary of the center sill. With image segmentation, smaller subregions embedded in the region occupied by the center sill can be identified and compared to the models developed for cracks (Fig. 13). The images collected in these tests were used to develop machine vision algorithms to analyze images of railcar underframes and assess the condition of certain structural components, such as bearing failure and broken wheels, two leading causes of freight-train derailments on mainlines.

Figure 13 A cracked center sill in the original digital image and segmentation images (Schlake et al., 2010).

Acoustic Emission-Based Detection

Equipment causes, such as bearing failure and broken rails, are also high-frequency derailment accident causes in the United States. In particular, the continuous increase in train operating speeds means that failure of a wheelset can lead to serious derailments, causing loss of life and severe disruption in the operation of the network. A method of wayside detection of axle bearing defects using time spectral kurtosis analysis on high-frequency acoustic emission (AE) signals was developed by Amini et al. (2016) in order to effectively prevent risks from defects. Instead of using the hot axle box detectors, which are commonly used to detect overheating axle bearings but cannot detect damage to axle bearings at its early stages, this wayside detection technology uses high-frequency AE to collect feedback about axle bearing defects and then process the signal to remove unwanted noise produced by the engine, wheel-rail interactions, and train acceleration/deceleration with spectral kurtosis, an analytical technique that measures kurtosis values in both the frequency and time domains. Both laboratory tests and field experiments were conducted to validate the feasibility of this axle bearing wayside detection technology (Fig. 14).

Human Factor-Relation Strategies

Positive Train Control (PTC)

Positive Train Control (PTC) or similar systems such as Automatic Train Control (ATC) have been used in Japan since the 1960s and in many European countries since the 1980s. For example, in Sweden, the development of ATC started in the 1960s and was formally introduced in the early 1980s, together with high-speed trains. By 2008, 9831 km out of the 11,904 km of track maintained by the Swedish Transport Administration—the Swedish agency responsible for railway infrastructure—had ATC installed. In the United States, it is still an emerging technology and its implementation was mandated by the Rail Safety Improvement Act (RSIA) of 2008. The territory of PTC implementation and operation in the United States includes Class I railroads, main lines servicing over 5 million gross tons (MGT) annually and over which toxic or poisonous-by-inhalation hazardous materials are transported, and main lines

Figure 14 Axle bearing detection in experimental work and field-testing configuration (Amini et al., 2016).

Figure 15 Architecture of PTC system (Zhang et al., 2018).

involving intercity and commuter passenger trains. PTC is a communication-based/processor-based train control technology that has the potential to improve safety because it provides a layer of additional protection beyond that provided by train crews and dispatchers (FRA, 2007b). More specifically, it can automatically prevent accidents attributable to human error by slowing or stopping trains, and is designed to prevent four major types of accidents: train-to-train collisions, derailments caused by excessive speeds, unauthorized incursions into work zones, and movements through misaligned switches.

The PTC system integrates the locomotive computer, wayside device, communication network, and back office to process collected movement authority and speed restriction data, and then compares these against the train's real conditions to ensure safety compliance (Fig. 15). With essential train information, such as real-time location, direction, and speed, if the PTC system were

Figure 16 Pulse electronics train Sentry III in an F-40 Cab (Oman and Liu, 2007). 4×3 LED array provides visual alert.

to determine the occurrence of a noncompliant train operation, then the PTC system would automatically apply the brakes and bring the train to a positive stop. Fig. 14 presents the network arrangement of various components integrated in PTC. For more technical details of the PTC system, refer to Petit (2009).

PTC describes a suite of train control standards. Railroads in the United States are allowed to install different PTC technologies in their respective systems once the types are approved and certified by the Federal Railroad Administration, including the Advanced Civil Speed Enforcement System, Interoperable Electronic Train Management System (I-ETMS), Enhanced Automatic Train Control (E-ATC), Incremental Train Control System (ITCS), Communications Based Train Control (CBTC), SafeNet System, and Sentinel System. In particular, ACSES and I-ETMS are two of the most widely implemented types of PTC system. In an ACSES-type PTC system, the ACSES system works in conjunction with the existing Automatic Train Control (ATC) system. Specifically, the ATC system ensures safe train separation and signal speed enforcement, while ACSES acts as an overlay to enforce civil speed restrictions (the maximum speed authorized for each section of track), temporary speed restrictions (e.g., temporary work zone), and positive train stops (PTS). One major feature of the ACSES-type PTC system is the employment of transponders. Differing from most types of PTC system that use GPS to identify train position, the ACSES establishes the train's exact position from the transponder sets it encounters. I-ETMS, by contrast, uses GPS to achieve train location and navigation information, and the locomotive segment monitors the train's real-time movement authority and speed, based on the collected information. The system would allow the train to proceed only if the switches are properly aligned and the speed limit is strictly observed. Unauthorized movement, overspeeding, or misaligned switches would result in penalty braking to slow the train down or even a PTS.

Engineer Education and Training

Heavy workloads, fatigue, monotony, and boredom in train engineers are found to be the issues leading to human error accidents (Dorrian et al., 2006). Fatigue is also responsible for a lack of attentiveness, which results in negligently disregarding signals or rules. Therefore, accidents caused by human errors may be reduced with periodic train operation education, a well-established working schedule, and an effective engineer fatigue monitoring program. Most incidents are linked to at least one organizational influence, which suggests that improvements in resource management, organizational climate, and organizational processes are important (Baysari et al., 2008). Train driving requires extensive knowledge of operation rules and vehicle behavior, along with the ability to integrate different static and dynamic sources of information (Giesemann, 2013); any failures of knowledge or ability may result in accidents due to violations of operation, mainline rules, or speed restrictions.

A variety of strategies and practices are being implemented on railroads. For example, a train driver training simulator was developed to train multiple drivers simultaneously and to review performance in detail (Rowe, 2013). This effective simulator includes the simulation of essential tasks (e.g., being able to look around while driving, taking power/applying brakes). Both normal and abnormal driving were documented in a full task list and analyzed with task assessment observations. To mitigate train engineer fatigue risk, a real-time online prototype driver-fatigue monitor was proposed by Ji et al. (2004). This non-intrusive monitor uses a prototype computer vision system for the real-time capture of video images of the driver and monitors the driver's vigilance. Similarly, cab alerts have been designed and implemented to alert the train crew by emitting a flashing light and an alarm (Oman and Liu, 2007) (Fig. 16).

Overview of Railroad Safety

Accidents on rail lines may be a collision between a highway vehicle, bicyclist or pedestrian and a train at a grade crossing, a collision between two trains, incidents involving pedestrians and other trespassers on rail property away from crossings, derailments, or any other events involving on-track equipment. In order to be reportable, the damage typically needs to be above an established threshold. Railroad accidents are rare compared to roadway accidents (annually around 17,000 railroad accident compared to over 7 million highway accidents in the United States) but the proportion leading to fatalities is higher (6%) compared to roadways (0.5%).

There has been a decline in the number of railroad accidents in the last 3 decades in the United States; yet, every year there are many railroad accidents. In the recent past, there has even been an increase in the number of trespassing and pedestrian related incidents. Trespassers have the largest share of the railroad fatal accidents in the United States, followed by railroad grade crossings (Fig. 1) (Savage, 2013). The distribution of significant railroad accident in the European Union is shown in Fig. 2 (European Union Agency for Railway, 2018).

Safety at Highway-Rail Grade Crossings

Highway-rail grade crossings are locations where a highway intersects with a railroad at the same level (at grade). In the United States, there are over 200,000 railroad grade crossings of which over 130,000 are public crossings. Accidents at the US grade crossings reached the lowest in 2007 (since the beginning of record keeping) but have remained nearly at that level for the past 10 years, as shown in Fig. 3. A similar trend is also observed in the EU where the number of accidents reached a low point in 2010 and has been more or less unchanged since then.

Most railroad crossings remain accident free year after year, but a small portion of the crossings has accidents in more than 1 year. There were 6301 public crossings in the United States that had a motor vehicle accident in the past 10 years (2009–18). Table 1 shows the number of years, in the 10-year time period, a crossing had accidents and its frequency. None of the 6301 crossings had accidents in 9 or more years out of the 10 years. Only one crossing had accident in 8 of 10 years, 216 crossing had at least one accident in 3 of the 10 years, 890 crossings had at least one accidents in 2 of the 10 years, and 5083 crossings had at least one accident in 1 of those 10 years. Each year around 700 crossings that did not have an accident in the previous year is seen to have an accident.

Reported Accidents at Railroad Grade Crossings

In the United States, the Federal Railroad Administration (FRA) redefined grade crossing collision in 1975 as any impact “between railroad on-track equipment and an automobile, bus, truck, motorcycle, bicycle, farm vehicle, pedestrian or other highway user at a rail-highway crossing (Ogden, 2007).” Before that, national statistics were limited to incidents involving a fatality, an injury to a person sufficient to incapacitate him or her for a period of at least 24 h, or more than \$750 in damage to railroad equipment or railroad track. This is however not the case in the EU, as the current legislation does not require the reporting of all railroad accidents by its member states. Accident reporting is limited to significant accidents or accidents defined by the EU as Common Safety Indicators (CSI).

Traffic Control Devices at Railroad Grade Crossing

The types of traffic control devices (TCDs) at a grade crossing could be broadly classified into active control devices and passive control devices. Active devices are those that warn a highway user of the train approaching or occupying the crossing. The most commonly used active TCDs include flashing light signals and gates. Other active controls include bells, wigwags, active advance warning devices, and highway traffic signals. Passive devices are those that are not activated by the train, and include pavement marking and signs. However, the trains themselves may have whistles acting as audible “active” warning signals at these locations. The number of accidents at active crossings is generally larger due to the high volume of vehicles and trains; however, the number of accidents at passive crossings normalized for exposure (or traffic moment = product of annual average daily traffic and average daily train traffic) is much higher than the rate for active crossings.

The type of warning device installed at a crossing is usually determined based on vehicle traffic count, type of vehicle using the crossing, number of daily trains and collision history at the crossing. Fig. 4 shows the number of US crossings by their warning device type. Around 50% of the public crossings are equipped with gates and 14% of crossings had flashing light warning devices without gates. Twenty five percent of the crossings have crossbucks. The remaining 11% have a variety of TCDs including stop signs, wigwags, etc. or have no warning device at all.

Gates

Gates are a type of active TCDs that function as a physical barrier across the highway lanes when a train is approaching or occupying the crossing. At a grade crossing, gates provide the highest level of traffic control and regulation. Gates are sometimes referred to as boom barriers.

Gated crossings are usually equipped with flashing light signals and crossbucks as well, as shown in Fig. 5. Most of the grade crossing incidents at gated crossings involved a motor vehicle going around the gate (around 30%) or stopped on the crossing (around 30%).

Flashing Lights

A standard flashing light signal in the United States consists of two red lights in a horizontal line flashing alternately at approaching highway traffic; the crossing is also equipped with crossbucks, as shown in Fig. 6. In some European countries, flashing light signals at crossings are sometimes also equipped with a white light which indicate to drivers and pedestrians that it is safe to cross the crossing. A high proportion (around 60%) of accidents at crossings with flashing lights involved motor vehicles that did not stop at the crossing.

Crossbucks

The railroad crossing sign or the crossbucks sign is a passive warning device that indicates a grade crossing. In the United States, crossbucks carry the word “RAILROAD CROSSING” written in black ink on a white background as shown in Fig. 7. Motorists

Figure 4 Percentage of crossings in the United States by warning device type. Source: FRA Office of Safety, 2019.

Figure 5 Railroad grade crossing with gates. Crossing is also equipped with flashing lights and crossbucks.

involved in accidents tend not to stop at crossings with crossbucks with over 60% of grade crossing accidents at crossbucks occurring to highway users that did not stop at the crossing.

Other warning devices at a highway-rail grade crossing include stop signs or other highway traffic signals, warning bells, wigwags, etc. Warning signs may be placed on crossing approaches to warn the highway user of an upcoming crossing known as advance warning signs, as shown in Fig. 8.

Operation of Active Control Devices

These control devices are activated by some form of train detection system. This is achieved either manually at a manned crossing or automatically using circuits within railroad tracks.

Figure 6 Railroad grade crossing with flashing lights.

Figure 7 Railroad grade crossing with only crossbucks.

Figure 8 Advance warning sign ahead of railroad grade crossing.

The train detection systems in use today include the following:

1. Direct current (DC) track circuit
2. AC–DC track circuit
3. Audio frequency overlay (AFO) track circuit
4. Motion-sensitive track circuit
5. Constant warning time track circuit

These detection systems operate in a way to provide a minimum of 20s of clearance time before the arrival of a train at the grade crossing. It is also important that the warning times provided at the crossing is not excessive as highway users could see this long duration as an equipment malfunction causing crossing violations (vehicle running around a closed gate) and accidents.

Interconnection and Preemption

If a highway–highway traffic signal exists close (within 200 ft.) to a railroad grade crossing location, the railroad and the highway traffic control may be interconnected (*Manual of Uniform Traffic Control Devices*, 2009). This allows for preemption of the highway traffic signal to increase safety at the grade crossing. Preemption of traffic signals is recommended if highway traffic queues have the potential for extending across a nearby rail crossing or if traffic backed up from a nearby downstream railroad crossing could interfere with signalized highway intersections. These recommendations are listed out by the Institute of Transportation Engineers (ITE) (ITE, 2006).

Preemption takes control of the traffic signal to provide for the safe passage of a train. Preemption of traffic signals allows for clearance of any queued vehicle on the crossing and prohibits any further movement of vehicles that would intersect the track. The preemption of the traffic signal occurs in three stages including entry into preemption, preemption hold, and exit from preemption. Entry into preemption happens when a train is detected and a call for preemption is sent to the highway signal. The mode of operation of the traffic signal is altered at this call. The preemption hold interval is active when the train is on the crossing. This remains on until the preemption input to the controller is removed. The purpose of the preemption hold is to ensure that the movements that do not interfere with the movement of the train may proceed. During the preemption hold period, all the movements that conflict with the train movement remains red while the other movements are allowed to proceed into the intersection. The traffic signal exits from preemption and enters its normal mode of operation after the train leaves the crossing.

Pre-Signal

Pre-signals are highway signals installed in front of railroad warning devices on a highway to stop the traffic before it crosses the railroad. A pre-signal shows red to an approach before the arrival of a train to prevent vehicles from entering the crossing. The vehicles already at the intersection are given the green signal so that they may clear. Pre-signals are installed in this manner to prevent vehicles from queuing across the grade crossing and finding themselves stopped on the tracks. The operation of pre-signals is integrated with the traffic signal preemption. In the United States, the *Manual on Uniform Traffic Control Devices* (MUTCD) lists out guidance for the use of pre-signals at grade crossings. **Fig. 9** shows a pre-signal.

Grade Crossing Elimination

Grade crossing elimination can be achieved by grade separating the crossing, by closing the crossing to highway and foot traffic or by closing the crossing to train traffic (abandonment of the rail line). Grade crossing elimination decisions are made by considering

Figure 9 Pre-signal indicating red to traffic approaching grade crossing.

safety, traffic operations, economic and social and environmental impacts, and costs. The benefits of eliminating a grade crossing are improved safety, reduced delay to train (trains tend to slow down at grade crossing) and highway vehicles, and avoidance of maintenance cost of crossing surface and TCDs.

Grade Separation

The highest level of traffic control and regulation for a grade crossing is the installation of crossing gates. If gates prove to be ineffective, a physical separation of the roadway and railway becomes necessary. Elimination of a grade crossing by the physical separation (grade separation) of the roadway and railway is called grade separation. Grade separation projects are costly and have long-term effects on the region and its users. Locations under consideration for grade separation should carefully be selected after considering several quantitative and qualitative factors.

Some of the techniques used to identify crossings for grade separation include multi-criteria assessment (MCA), cost benefit analysis, trade off analysis, etc. In the United States, the *Highway-Rail Grade Crossing Handbook* lists out several warrants to be considered before elimination of a grade crossing via grade separation (e.g., grade crossings should be considered for grade separation, if the maximum authorized train speed at the crossing exceeds 110 mph).

Potential Grade Crossing Safety Contributing Factors

The variables included in the model represent the traffic and geometric features of the crossing. Most hazard models developed for railroad grade crossings use annual average daily traffic (AADT) and train volume at the crossing in the original, or in a transformed form, or as a function of the two variables. Other variables include train speed, highway speed, number of highway lanes, number of train tracks, etc. Additional variables including the smallest angle between highway and rail track, distance to highway intersection, etc. are included in later models. The variables used in the hazard models could be categorized into safety-related variables, traffic-related variables, location, and crossing geometry variables. Other variables including economic development in the region, vehicle type using the crossing, community consideration (vulnerable population living near the region, use of grade crossing by emergency vehicles/school bus), etc., which could influence the hazard model, has not been included in any models so far.

Modeling Safety at Railroad Grade Crossings

Quantifying safety at highway-rail grade crossing is carried out to identify the crossings with high safety risk. Several hazard indices to identify the riskiest crossings for crossing closure or other safety improvements have been developed worldwide.

Modeling of safety at railroad grade crossings allows predicting the number of collisions, predicting the severity of accidents, prioritizing crossings for safety upgrades, or identifying patterns in accidents at an individual crossing or a group of crossings. In the United States, the USDOT accident prediction formula is used to predict the number of collisions at grade crossing locations.

Tools like static tree and dynamic tree methods to visualize accident patterns by identifying the highest accident-contributing factor have also been developed. **Fig. 10** shows the accident visualization at an individual crossing using dynamic tree at a crossing showing all six accidents at the crossing involving an eastbound vehicle and eastbound train possibly indicating an issue due to a tight crossing angle.

Trespassing and Pedestrian Safety

Trespassing is defined as “persons who are on the part of railroad property used in railroad operation and whose presence is prohibited, forbidden or unlawful.” The motive for trespassing is usually when a person uses the railroad right of way as a shortcut, for graffiti or criminal purposes, or for suicide. Trespassing is a complicated problem to address from a community perspective because trespassing incidents only constitute around 2% of all public safety issues including homicides, illegal drugs, highway crashes, etc.

In the United States, trespassing-related railroad incidents result in higher number of fatalities than all other categories combined. In 1997, the number of trespasser fatalities exceeded the number killed in collisions at grade crossings for the first time since 1941. In 2017, there were over 500 fatalities due to trespassing incidents as compared to around 200 fatalities due to railroad grade crossing incidents. A lack of knowledge and appreciation of the dangers of trespassing accidents contributes to a very high fatality rate for trespassing incidents. Fatalities due to trespassing-related incidents may be characterized as intentional (suicide) or unintentional. A fatality due to a trespassing incident is determined to be a suicide by a coroner or a medical examiner. When the medical examiner or coroner reports that the cause of a rail fatality is undetermined, it is recorded as a trespass death.

Between 2012 and 2014, there were over 3500 trespassing incidents recorded in the United States with over 1700 of those incidents resulting in a fatality. In this time, there were an additional 700 suicides as well (as determined by a coroner). Each year, on an average there are over 450 trespassing-related fatalities, 490 trespasser injuries, and around 200 suicides on rail property.

Pedestrian Safety at Railroad Grade Crossings

The number of pedestrian accidents at public grade crossings is showing an increase from 125 accidents in 2008 to nearly 200 incidents in 2018. The number of pedestrian accidents that were fatal also saw an increase in these years. The proportion of pedestrian accidents that resulted in a fatality reached a peak in 2016.

Pedestrians can easily enter a crossing as compared to motor vehicles as they usually do not see themselves as part of the traffic. As a result, pedestrians tend to ignore warning devices. Other factors that are relevant to pedestrian violations at grade crossings, include time of day, age, gender, inattention, time pressures, the number of pedestrians present, the influence of alcohol or drugs, mental illness, and thrill-seeking behavior. Effective use of channelization devices can direct the flow of pedestrians to one point at the crossing. Such devices have shown to improve the safety of pedestrians at crossings.

Figure 11 Pedestrian Accidents at the US grade crossings.

Most of the pedestrian incidents at railroad grade crossings involve males (around 75%), and occur during clear days (around 70%), and show a decline in winter months.

Emerging Technologies to Improve Railroad Safety

Several emerging technologies have been developed which are playing a role in improving the safety of railroad users, for example, intelligent transportation systems (ITS). In railroad applications, ITS technologies can enable improved warning of approaching trains to motorists and pedestrians. They can also be used to reroute traffic around blocked or busy grade crossings to alleviate congestion. Several projects carried out indicate that ITS technologies can have a positive impact in increasing safety and mobility at railroads.

Intelligent Transportation Systems in Railroads

ITS is the application of communication, control, and information exchange technologies, to transportation systems operation and management. Communication between vehicles and infrastructure is enabled by various wireless technologies including, dedicated short-range communication (DSRC), radio modem using ultra high frequency (UHF), wireless communication, etc. Communications between the vehicles and infrastructure can facilitate quick information exchange to warn a driver of an upcoming crossing, alert a locomotive engineer about changes in crossing signals/crossing status.

The Federal Communications Commission (FCC) has set aside 75 MHz of spectrum in the 5.9 GHz band in the United States to be used for vehicle-related safety and mobility systems ([Federal Communications Commission, 1999](#)) while the European

Figure 12 Number of pedestrian accidents by type of crossing warning device in the United States (2012–18).

Telecommunications Standard Institute (ETSI) has allocated 30 MHz of the 5.9 GHz. Some of the applications of ITS involve positive train control, connected vehicles, etc.

Positive Train Control

Positive train control (PTC) is a train control system which only allows train motion so as to prevent train-to-train collisions, derailments caused by excessive speed, unauthorized train movement onto sections of track where maintenance activities are taking place, movement of a train through a track switch left in the wrong position. PTC system cannot prevent grade crossing collisions (Federal Railroad Administration, 2018).

A PTC system can determine a train's location, speed, and direction. This is achieved with two basic components. They include the control unit on the locomotive and a system to communicate with the control unit about changing conditions within the track. The control unit receives information from wayside stations along the planned route of the train giving the locomotive engineer advanced warning. The system automatically applies brakes to the train, if no action is detected from the locomotive engineer.

Positive train control was recommended by the National Transportation Safety Board (NTSB) in the United States in 1990 and has been implemented more-or-less system-wide in many other countries. PTC implementation was made mandatory for most Class 1 railroads by law in United States congress via the Rail Safety Improvement Act of 2008. The system is expected to be fully interoperable by 2020.

Connected Vehicles

Communication between the crossing and a connected vehicle (a vehicle which can communicate with other vehicles or infrastructure) can alert the driver of a highway vehicle about the status of a crossing, and thereby avoid an incident.

Connected vehicles often have an on-board equipment (OBE) that provides communications, sensory, and processing functions to support the safe operation of the vehicle. The radios supporting vehicle to vehicle (V2V) and vehicle to infrastructure (V2I) communications are a key component of the OBE to enable in-vehicle warning to the highway vehicle about the occupancy of a crossing by the train.

Detection Technologies for Pedestrian Detection

Video data has been used for surveillance of railroad property. Advances in machine learning techniques have enabled the automation of pedestrian detection from video data. Such technologies show promise in automating labor-intensive work and can support data driven research on trespassing safety.

Introduction

Boating is a popular recreational activity in many high- and middle-income countries (Peden et al., 2018a). In low-income countries, boating is often used for non-recreation purposes and predominately as part of daily living, such as for transportation purposes, or used occupationally (World Health Organization, 2014). This chapter focuses on recreational boat and watercraft usage only. Despite its popularity, recreational boating is not without risks. This chapter unpacks these risks and offers solutions to improve boating safety. It first focuses on exposure through usage and location data, and then reports on the epidemiology of death and causes of injury. This chapter then moves on to discuss common risk factors associated with recreational boating including operator inexperience, improper lookout, excessive speed, overloading, alcohol and other drugs, and nonuse or unavailability of life jackets. The chapter concludes with implications for prevention to reduce boating risks including safe boating strategies, legislation and regulatory strategies, and social psychological and behavioral strategies.

Explanation of Terms Used

Boating and non-powered watercraft can be used for recreational (i.e., leisure pursuits) and non-recreational (i.e., daily living or occupational) purposes. This chapter focuses on recreational usage of boats and watercraft only. It must be noted that boating and watercraft differ. Boating is defined as the act of using water-based wind or motor-powered vessels, boats, ships, and personal watercraft (PWC) (e.g., jet skis, sailboats, yachts, and catamarans) (Australian Water Safety Council, 2016). Watercraft, on the other hand, is defined as water-based non-powered recreational equipment such as those that are rowed or paddled (e.g., rowboats, surfboards, kayaks, canoes, stand-up paddleboards [SUPs], boogie boards, windsurfers, inflatable rafts, and inflatable boats without motors) (Australian Water Safety Council, 2016). Fatal and non-fatal drownings are also discussed in this paper. Drowning is defined as “the process of experiencing respiratory impairment due to immersion/submersion in a liquid (van Beeck et al., 2005).” Outcomes of this process are defined as death (fatal drowning), morbidity or no morbidity (non-fatal drowning) (Peden et al., 2018b). Drowning can be intentional (e.g., self-harm, assault, and homicide) or unintentional (i.e., accidental) in nature. Where drowning is referred to in this paper, it refers to unintentional drowning.

Exposure: Usage and Location

Recreational boating (including the use of watercraft) is a popular activity in many high- and middle-income countries; however, global estimates of usage are difficult to derive. From reports available, estimates of the economic impact of the global recreational boating market indicate it is expected to reach an estimated \$30 billion United States Dollars (USD) by 2022 (Global News Wire, 2018).

United States

The United States (US) Coast Guard, through its National Recreational Boating Survey (NRBS), estimates there are 22.28 million recreational boats in the United States with 3.58 million boating person-hours undertaken in 2012. It is estimated that 23.9 million people in the United States undertake paddling activities per year, with canoeing (10.1 million) being the most popular activity, followed by recreational kayaking (6.2 million) (United States Coast Guard, 2012).

Canada and Europe

In Canada, it is estimated that 46% of Canadians aged 18 years and over went boating in 2014 (approximately 13.2 million Canadians), with ownership estimated at 8.6 million boats. European estimates indicate there are 36 million boaters across Europe, with 6 million boats in European waters and a further 48 million people enjoying watersports (Boating in Canada, 2019).

Australia

National estimates from Australia report 5 million recreational boaters in Australia. A total of 2 million Australians are estimated to hold a boat license. There are more than 900,000 registered boats in Australia, with as many as 900,000 watercrafts such as paddlecraft, SUPs, and sailing dinghies that do not require registration. The boating fleet is growing by 15,000 new registrations nationally per year. In Australia, PWCs are the fastest growing sector of powered vessels with 68,000 registered in Australia (as of 2017) ([Boating Industry Association, 2017](#)).

Locations and Hazards

Boating and watercraft activities can be undertaken in a range of environments, each with their own unique hazards and risks. Rivers and inland waterways such as lakes and dams are commonly known for their cold, murky water, which often conceals strong currents, submerged objects and shifting slippery banks and beds. By contrast, coastal locations can be prone to strong currents and large and unpredictable waves that are often weather dependent.

In the United States, the NRBS estimates that inland lakes are the leading location for boating, with 57% of the estimated 244 million boating days taking place on inland lakes, followed by rivers (21% of all boating days). Powerboats are most commonly used at freshwater locations, whereas sailboats are more commonly used in saltwater locations. Paddlecraft are used primarily on lakes and rivers ([United States Coast Guard, 2012](#)).

In Canada, boating and watercraft usage most commonly occurs in inland waterbodies such as lakes, ponds, rivers, creeks, streams, or waterfalls. In Europe, inland waterways, as well as offshore boating along the coast, are popular ([Boating in Canada, 2019](#)). In Australia, as in Europe, both inland and coastal waters prove popular for boating, with watercraft users, such as kayakers and canoeists more commonly preferring inland locations such as rivers and lakes ([Pidgeon and Mahony, 2016](#)).

The Epidemiology of Death and Causes of Injury

Drowning is a leading cause of death during boating- and watercraft-related activities, with other causes often injury-related ([World Health Organization, 2014](#)).

United States and Canada

In the United States and Canada, the number of transportation fatalities from recreational boating rank only second to motor vehicles compared with other modes of transportation. In 2017, the US Coast Guard counted 4291 accidents that involved 658 deaths, 2629 injuries, and approximately \$46 million USD in damage to property as a result of recreational boating accidents. When exposure is considered, the NRBS fatality rate for the United States (as calculated as a ratio of the number of deaths per 100 million exposure hours) was highest for rivers with approximately 27 deaths. By contrast, bays had the lowest fatality rate at 12 deaths per 100 million exposure hours ([United States Department of Homeland Security, 2018](#)). To put this risk in perspective, the United States saw 24,973 accidental deaths among motor-vehicle occupants in 2017 if motorcyclists are excluded. And, Americans are estimated to have traveled around 119 billion hours by cars and trucks in 2017. This gives a fatality risk of 21 per 100 million exposure hours for vehicle occupants. In other words, on average, boating seems to be a slightly more dangerous activity than traveling in a motor vehicle. In Canada, boating accounted for 34% ($n = 2323$) of the 6811 water-related fatalities in summer from 1991 to 2013 ([Red Cross Canada, 2016](#)).

Australia

In Australia, 20% of all unintentional fatal drownings are due to boating and watercraft incidents; it is the second leading cause of drowning in Australia after swimming. Across a 10-year period (2005/06–2014/15), a total of 473 people drowned while participating in boating- or watercraft-related activities. Of these, 92% were male, and incidents most commonly occurred while fishing (28%), while the vessel was underway (27%), or due to a fall overboard (12%). Ocean/harbors were the leading location for boating- and watercraft-related drowning fatalities (51.9%) ([Willcox-Pidgeon et al., 2019](#)).

Sweden

As an example of drowning deaths in Europe, we can look at Sweden, a country with 10 million inhabitants and 820,000 recreational boats. In 2018, Sweden saw 135 drowning fatalities, or 1.4 drowning deaths per million inhabitants. This number is similar to what has been experienced since the early 1990s. Before that, Sweden saw many more fatal drownings with a rate of over 4 per million inhabitants in the 1960s and around 3 per million inhabitants in the 1970s. Of the people drowning in 2018, 87% were male, 16% were above age 70, and 10% were children below age 19. Just over one-third of the drownings happened in connection to swimming, 11% by people falling through ice, and 9% (12 people) in connection to recreational boating. However, 2018 is an outlier with respect to recreational boating fatalities. The average for the last 10 years is 25 per year or about 20% of all

drownings. Less use of alcohol on boats and higher use of life jackets explain the reductions in drownings since the 1960s, but the drowning rate is still considered unacceptable by the Swedish authorities and a goal of cutting the number of drownings by 50% by 2030 is a step toward a Vision Zero for boating deaths. The previous goal was set to reduce recreational boating deaths from 40 to 25 deaths per year by 2020, and that goal seems to be reached. During the 1970s, the average was around 90 deaths per years in recreational boating accidents.

Small Boats

The World Health Organization (WHO) reports data from countries such as Australia, Canada, Germany, Finland, and the United States, and suggests the number of deaths related to incidents involving small boats (i.e., boats ranging from 5 to 8 m [16–26 ft.] in length) form a significant proportion of all drowning fatalities ([World Health Organization, 2014](#)). In Canada, powered boats 5.5 m (18 ft.) and under accounted for 47% of all summer boating-related fatalities ([Red Cross Canada, 2016](#)). In Australia, powered boats accounted for 71% of all boating- and watercraft-related drowning deaths, with the highest occurring in boats 5 m (16 ft.) and under in length (30%) ([Willcox-Pidgeon et al., 2019](#)).

Injuries

There are a range of other causes that can lead to injuries and fatalities when participating in boating- or watercraft-related activities. These include traumatic injuries and blood loss from propeller strikes ([Mann, 1980](#)), spinal injuries, and concussion among others. Carbon monoxide (CO) poisoning has also been responsible for deaths while boating ([Yoon et al., 1998](#)).

Personal Watercraft

A study of PWC-related injuries and fatalities in Arkansas identified 126 incidents involving 141 vessels and over \$156,000 USD in property damage for the years 1994 through 1997 ([Jones, 2000](#)). Almost two-fifths of PWC users were injured, mainly head trauma and fractures to the lower limbs. There were five reported fatalities. The most common injuries by type were lacerations (14%), fractures (13%), and contusions (7%). When examined by body region, injuries commonly occurred to the lower extremity (21%), followed by head and neck (14%) and the upper extremity (7%).

Canoeing, Kayaking, and Rafting-Related Injuries

An examination of injuries related to canoeing, kayaking, and rafting found aside from death, other hazards encountered include hitting objects, waterborne diseases, hypothermia from unintended submersion, blisters, muscle strain, cuts, and abrasions ([Franklin and Leggat, 2012](#)). The body areas more commonly injured when undertaking paddling-related activities were the face (33%) (including the eye, mouth, nose, and teeth), knee (15%), arm/wrist/hand (12%), and other parts of the leg/hip/foot (11%). Common contributing factors for canoe deaths and injuries recorded by the US Coast Guard included alcohol use (18%), hazardous waters (18%), improper loading (13%), operator inexperience (13%), and weather (8%). For kayak-related deaths, the most common contributing factor identified by the US Coast Guard was hazardous waters (45%) ([United States Department of Homeland Security, 2018](#)).

Propeller Strike

Propeller strike is another cause of serious injury and, in severe cases, fatality. Traumatic injury including cuts and blood loss can be caused by contact with a boat propeller and, in severe cases, amputation of limbs can occur ([Mann, 1980](#)). Most amputations occur to the lower extremities. Wounds resulting from propeller strikes are also prone to infections due to contaminated water with seawater and inland water often having different bacteria present.

Carbon Monoxide Poisoning

CO poisoning is a serious hazard associated with recreational boating. A study of 512 patients treated for acute unintentional CO poisoning identified that individuals commonly lose consciousness as a result of the poisoning. Most cases occurred aboard a boat that was older than 10 years, had an enclosable cabin, was longer than 6.7 m (22 ft.), was powered by a gasoline engine, and was without a CO detector on board ([Yoon, 1998](#)).

Risk Factors

Common risk factors contributing to boating deaths, injuries, and accidents worldwide are now discussed. Other risk factors not mentioned include preexisting medical conditions, poorly maintained vessels, older vessels, and small vessels (see small boats).

Injury and Fatality Risk Factors

A US study of boating-related injuries and fatalities in Washington State found factors, such as not wearing a life jacket, not having safety features present, being on an unpowered boat, having alcohol present (Stempski et al., 2014), boating in the ocean, boating between the hours of midnight and 5:59 a.m., incidents involving capsizing, sinking, flooding, or swamping, and incidents that involve a person leaving the boat voluntarily, ejected or due to a fall increased the chances of being fatally injured.

Operator Inexperience, Inattention, and Poor Judgment

Boating accidents are largely attributed to lack of experience, not paying attention, and poor judgment largely due to human error (United States Department of Homeland Security, 2018). Technical knowledge and experience of how to operate a boat, whether a small 5 m (16 ft.) dingy, a 3 m (10 ft.) sailing vessel, or a canoe, is essential to avoid accidents, injuries, and death on the water. This includes failure to perceive or observe danger outside or inside of the boat. Examples of incidents resulting from operator inexperience and/or inattention include hitting submerged objects; beaching on shallow water, sandbanks, or rocks; other boats or people in the water; and persons falling overboard. Of the known causes, human error is responsible for 33% of fatalities in New South Wales, Australia (Transport for New South Wales, 2018).

Improper Lookout

The operator/skipper is responsible for keeping a lookout for dangers at all times, by sight and hearing, especially in poor weather conditions, when dark or in limited visibility, and in waterways with high traffic. Most jurisdictions require having an appointed “lookout” or “observer,” when towing, for example, water skis, tubes, etc. This individual is responsible for looking out for persons overboard, other boats, or hazards, and for giving the skipper instructions in regards to speed and directions.

Excessive Speed

Excessive speed is one of the top five causes of boating-related deaths and injuries in the United States, Canada, and Australia (Red Cross Canada, 2016; Transport for New South Wales, 2018; United States Department of Homeland Security, 2018). Speed restrictions exist for vessels, similar to that of road users. For example, the five-knot rule applies when within 200 m (656 ft.) to shore, near other boats, dive buoys, or people. Similar to excessive speeding in a motor vehicle, there may be a high chance of a high-impact collision, and the vessel may capsize. Additional speed restrictions may apply when towing (e.g., water skiing, using PWC).

Alcohol (and Other Drugs)

The role of alcohol and driving a motor vehicle is well reported; however, there is less information available on alcohol and boating. Boating-related fatality statistics attribute alcohol as a leading cause of boating accidents, injuries, and deaths. Alcohol alters perception, judgment, and balance. The link between alcohol and drowning is evident, especially among men (Hamilton et al., 2018). Some medications may cause drowsiness; thus, checking medication packages for cautions and discussing with a medical professional before operating a vessel and taking medication (including mixing with alcohol) is recommended.

In Sweden, alcohol was involved in 75% of all recreational boating fatalities in 2012 where blood alcohol concentration (BAC) was measured. However, autopsies were performed in only about half of all cases, so the actual rate may be lower. By 2015, that percentage had dropped to 60%. Many of the alcohol-related fatalities occur in harbors when people walk between boats and not during the operation of boats. Since 2010, Sweden has a 0.02% drunk driving law for operating boats, but it applies only to the operator (and other people onboard responsible for passengers’ safety) and only to boats that can achieve 15 knots.

Life Jackets

Not wearing life jackets (also known as personal flotation devices [PFDs]) has been well established as a contributing factor for drowning during recreational boating, both powered and non-powered. The risk of drowning and hypothermia increases when not wearing a life jacket. Life jackets have been found to increase the chance of survival in the water by 50% (Cummins et al., 2011); however, many studies report a low level of wearing life jackets, with the exception of children. In many jurisdictions, it is mandatory to carry life jackets for everyone on board the boat, but it is not necessarily mandatory to wear them. Barriers to life jacket wear have been explored including cost, comfort, risk perception, and role modeling with children (Peden et al., 2018a). Studies have shown that children are more likely to wear life jackets than adults. In addressing comfort, inflatable slimline life jackets have been available for a number of years as an alternative to the foam block style life jackets. While these life jackets have decreased in size and cost, and increased in comfort and ability to move more freely, issues regarding the CO₂ canister have arisen, where the life jacket has not deployed due to the canister becoming unattached, rusted, or leaking. Manufacturers recommend servicing these life jackets every 12 months.

Weather

Weather influences boating activity, with favorable weather making it more attractive to be on the water for a range of activities, increasing exposure, and therefore risk (Fralick et al., 2013). Marine weather can be very different to weather on land, with conditions out at sea or over open water changing quickly and impacting water and wave conditions. Weather reports, including wind direction, wave height, and tide times, are usually broadcast over marine weather channels on very high frequency (VHF) radios, on websites, and, more recently, on boating apps. Water temperature around the world varies, and hypothermia is life threatening in the case of falling overboard or capsizing. Life jackets can help retain heat when in the water.

Rules Violation

International maritime rules are implemented worldwide (World Health Organization, 2014), and are designed to provide a safe environment for all water users and to decrease the risk of accidents, injuries, or death while on the water (e.g., life jacket carry and wear, restricted speed, and alcohol limits for operating a vessel). Local jurisdictions often add to these rules to reflect the local environmental conditions. Violating rules such as excessive speed or consuming alcohol while operating a vessel places not only the operator/skipper in danger, but also their passengers and other waterway users. The consequences of violating rules vary from fines, license suspension, and having the vessel impounded, to criminal charges being laid, especially if people are injured or killed (Willcox-Pidgeon et al., 2019).

Overloading

Overloading of boats, especially small boats, with people, cargo, or seafood, is a common occurrence worldwide. Every boat has a limit of how much weight it can safely carry without compromising stability. Overloading can unbalance the boat and cause tipping or capsizing of people and goods, especially in unfavorable weather and water conditions, and especially in small vessels that are already low to the water (World Health Organization, 2014).

Strategies to Improve Safety

This section discusses strategies to improve recreational boating safety, including safety equipment, legislation and enforcement, and behavioral strategies.

Safe Boating Strategies

Safety equipment is essential when boating regardless of experience, type of vessel, or duration on the water. Universally, the minimum recommended safety equipment includes items such as life jackets, anchor and line, distress flares, EPIRB, and marine radio (VHF) (Boating Industry Association, 2019; Stempski et al., 2014) (Table 1). Although these items are universal, recommended equipment may vary depending on type of vessel and environment.

Before going out on the water and during boating activity, it is important to check the weather and water conditions and to familiarize oneself with the general location. Logging trips on and off with local marine organizations (e.g., coast guard, marine rescue) will ensure that the vessel's general location and expected time of arrival is known. This is especially important if something unexpected were to happen.

In the event of the vessel capsizing or an unexpected fall into the water, life jackets can help retain heat when in the water. The following techniques are designed to increase survival when in the water:

- HELP: Heat escape lessening position—arms across chest and bring knees up to chest (Fig. 1).
- Huddle: Huddling close together with other people by linking arms, retaining body heat (Royal Life Saving Society - Australia, 2016).

Legislation and Regulatory Strategies

The WHO Global Report on Drowning proposes the “setting and enforcement of safe boating, shipping, and ferry regulations” as one of 10 key strategies for reducing the global drowning burden (World Health Organization, 2014).

Table 1 Recommended minimum safety equipment

<i>Recommended minimum safety items for recreational boating</i>	
Life jackets	Fire extinguisher
Anchor and line	EPIRB
Bailer or bucket	Marine radio (VHF)
Bilge pump	Waterproof torch
Distress flares	Compass
Oars/paddles	

Figure 1 The HELP position. Source: *Royal Life Saving Society - Australia, 2016*

Legislation in many countries requires carrying the appropriate number of life jackets for everyone on board. Furthermore, mandatory wearing of life jackets in boats 6 m (20 ft.) and smaller to prevent injuries and drowning in these vessels was introduced to address the high number of incidents in these small vessels. The success of such legislation is evident, in Tasmania, Australia. Tasmania was the first jurisdiction in the world to introduce this legislation in 2001 and currently reports a 90% life jacket wear rate (Willcox-Pidgeon et al., 2019). In Victoria, Australia, and Washington State, the United States, decreases in boat-related drowning deaths have been reported since introducing mandatory wearing of life jackets in small boats (Bugega et al., 2014; Chun et al., 2014). Enforcement of life jacket legislation can be done through random checks on board vessels and at boat ramps, with punishment ranging from warnings to fines and loss of license (where such licensing schemes exist) (Stempski et al., 2014).

Many developed countries require an operator or skipper to have a license to operate a recreational vessel. License testing generally includes basic boating theory and knowledge including maritime rules, speed, give-way rules for different types of vessels (powered and unpowered), safety requirements, communication, and marine weather. Examples from Australia indicate that operator licensing has been found to increase awareness and knowledge of the boating public and decrease incidents (Virk and Pikora, 2010).

Many high-income countries (such as the United States, Australia, and Canada) impose alcohol limits for people operating a recreational vessel, with some jurisdictions implementing alcohol breath testing and drug testing on the water. The limits in Australia, United States, Canada, and Europe are BAC of ≤ 0.05 mg/L. Consequences for operating a vessel under the influence may include fines, loss of license, and the vessel being impounded (Willcox-Pidgeon et al., 2019).

Social Psychological and Behavioral Strategies

It is often assumed that people engage in unsafe recreational aquatic activities, including unsafe boating behaviors such as not wearing a life jacket and consuming alcohol while boating (Hamilton et al., 2018; Peden, et al., 2018a), because of a lack of knowledge of the risks. This belief has given rise to numerous public health campaigns that have focused their attention on raising knowledge and awareness of the dangers involved in risky boating-related recreational activities. However, given the increased attention that the issue of boating safety has received in both media coverage and public health messages, particularly in developed countries, the dangers are known to many. Despite this, people continue to ignore safety warnings and carry out unsafe behaviors while boating. This highlights that having the correct information does not always translate into behavior change, suggesting that risky acts while boating are based on more than knowledge acquisition alone.

Recent research has provided emerging evidence for the social psychological and behavioral factors that may influence individuals' decisions in, on, and around water (Hamilton et al., 2016; Hamilton et al., 2014; White et al., 2018). Given psychological factors are likely to be critical in individuals' decisions to engage in risky aquatic activities, including recreational boating, it is important that interventions grounded in sound psychological and behavioral theory be adopted to modify people's risky boating behaviors. This is especially important given research has shown theory-based campaigns may be more effective in promoting health- and risk-protective behaviors compared to atheoretical ones, and evaluation of advertising countermeasures is easier and more cost-effective with theoretically devised approaches given the clearly measurable constructs (Prestwich et al., 2015; Noar, 2006).

In examining the current literature, limited research has been conducted in this area and, in particular, related to recreational boating safety. Drawing on the literature more broadly, several social psychological and behavioral factors have been identified that may influence individuals' decisions to engage in risky aquatic activities. These include past experience, attitudes (i.e., costs and benefits), social pressure and norms, self-efficacy beliefs (i.e., motivating or inhibiting factors), planning, anticipated regret (i.e., anticipated emotions experienced), and risk perceptions (i.e., weighing up the risks involved and possibility of adverse consequences) (Hamilton et al., 2016; Hamilton et al., 2014; White et al., 2018).

Given the little evidence that promoting awareness and knowledge alone results in sustained changes in behavior, it seems important to draw on these more social psychological and behavioral factors when designing campaigns aimed at improving boating safety to ensure the messages embedded within the campaigns will be effective in changing people's behavior. For example,

promotion efforts to improve safe recreational boating behavior may consider using behavior change methods such as persuasive messaging to change attitudes, building self-efficacy to overcome barriers, harnessing normative influences, and encouraging people to plan their behavior prior to going boating. It is also important to consider the framing and content of safety messages when attempting to change behavior through emphasizing the negative consequences of behaviors. For example, campaigns using *fear appeals* that seek to elicit an emotional response of fear to encourage behavior change have been shown to be mostly ineffective, and in some cases have adverse effects (Peters et al., 2013). The exception is that when fear appeals are accompanied by tangible resources to increase self-efficacy toward the behavior seeking to be changed, small effects can be attained. In contrast, gain-framed messages emphasizing the positive consequences of engaging in the desired behavior tend to be more effective because they are more readily accepted and prevent defensive and avoidant reactions.

Conclusion

Boating and watercraft use are popular activities. Tens of millions of people participate recreationally in boating and watercraft activity; however, participation is not without risk. Injuries or death, most commonly as a result of drowning, can occur and it is important that participants are mindful of the risks. Such risk factors that may impact safety include operator inexperience, improper lookout, alcohol and other drugs, excessive speed, lack of life jackets, and overloading among others.

There are a number of strategies to reduce risk and increase the safety of recreational boaters and watercraft users. These can be loosely grouped into safe boating strategies with an emphasis on safe behavior, vessel seaworthiness and safety equipment, legislation and regulatory strategies, and social psychological and behavioral strategies.

Biographies

Amy Peden has extensive experience in drowning prevention research, policy, and practice. She has authored over 40 peer-reviewed articles to date, as well as over 60 professional reports. She has been a key contributor to the last three Australian Water Safety Strategies. She is currently a Senior Research Fellow with Royal Life Saving Society - Australia (RLSSA). In her previous position as National Manager of research and policy with RLSSA, her duties include the production of the National Drowning Report, maintaining the National Fatal Drowning Database, analyzing policy, and evaluating programs. She is a PhD candidate at James Cook University researching the epidemiology, risk factors, and prevention strategies for unintentional river drowning.

Stacey Willcox-Pidgeon is the Senior Research and Policy Officer with Royal Life Saving Society of Australia. She has conducted a range of drowning-related research, analysis, and program evaluation in Australia and New Zealand. She has authored drowning research publications, professional reports, and presented at a range of national and international conferences. She completed a Master of Public Health Research Thesis in 2015 investigating youth risk perception of drowning in a beach environment. She has recently commenced a PhD focusing on drowning prevention for high-risk populations in Australia.

Dr. Kyra Hamilton is an Associate Professor in health psychology and behavioral medicine in the School of Applied Psychology at Griffith University, Australia. She has both psychology and nursing qualifications and over 25 years' experience in the health field. She has particular research interests in health behavior motivation, self-regulation, and change. She has won national and international awards for her research and is Chief Investigator on national competitive, industry, and internal grant funded projects. She is the founder and director of the Health and Psychology Innovations (HaPI) research laboratory.

Introduction

Refuge comes from *refugium* in Latin, shelter or retreat place. It is often also referred to as safety island, safety area, traffic island, or refuge island.

A refuge is a solid or painted object in a road. If the island uses road markings only, without raised curbs or other physical obstructions, it is usually called a *painted island*.

Pedestrian Crossings

Well into the 1800s, pedestrians ruled our streets even if in some competition with horses and toward the end of the century bicycles. Then when steam-powered vehicles started to arrive, regulations ensured low vehicular speeds. For example, the “Red Flag Act” was passed in the United Kingdom in 1865 and not repealed until 1896. It restricted the speed of horse-less vehicles to 4 mph (6 km/h) in open countries and 2 mph (3 km/h) in towns. The act required one person to walk ahead carrying a red flag. In 1896, the speed limit was raised to 14 mph (23 km/h) and the need for the escort was removed and then in 1903 to 20 mph (32 km/h). That speed limit was kept until 1931. Similar Red Flag Acts were enacted in many US states and were kept into the 20th century, though the urban speed limit varied between different jurisdictions and was typically 5, 10, or 12 mph (8, 16, or 19 km/h). At those speeds, it was typically easy for pedestrians to safely cross streets. That all changed with mass motorization. Higher speed limits were enacted and most countries gave automobiles the right of way and pedestrians had to look for gaps between cars, especially if crossing away from marked crosswalks. And, even in crosswalks, the practice in most countries became that pedestrians had to look for gaps between cars. Putting a refuge island in the middle of the street facilitated finding such gaps. In the last couple of decades, more and more jurisdictions have given absolute priority to pedestrians in crosswalks, and, at least in theory, pedestrians should be able to walk from curb to curb blindfolded, whereas motorists should be responsible for finding gaps between pedestrians. When we reach such a situation, there will be little need for refuge islands at pedestrian crossing points, but we are certainly not yet there.

Crossing the street can be a complex task for pedestrians, especially for those who are less capable of handling traffic. Pedestrians must estimate vehicle speeds, adjust their own walking speeds, determine adequacy of gaps, predict vehicle paths, and time their crossings appropriately. Drivers must see pedestrians, estimate vehicle and pedestrian speeds, determine the need for action, and react. At night, darkness and headlamp glare make the crossing task even more complex for both pedestrians and drivers. A refuge allows pedestrians to cross one direction of vehicle traffic at a time. The refuge provides some protection from traffic in the center of the road, while the pedestrian waits for a safe gap in the second direction of traffic.

Refuge islands significantly improve amenity for pedestrians trying to cross busy streets, as they are much more likely to find two long-enough gaps in traffic rather than one situation in which gaps for both directions coincide. Since this reduces pedestrians’ average waiting time, it also improves safety, with impatient pedestrians less likely to use gaps that turn out to be too short for safe crossing. Traffic islands can also contribute to a channelization of pedestrians. As Huang and Cynecki (2001) found, more pedestrians use a channelized pedestrian crossing instead of using other crossing locations. That, however, presupposes that

pedestrians actually feel that they are helped by the crossing, for example, that motorized traffic is stopping/yielding more often at that crossing compared with another crossing site.

Generally, research has indicated that safety for pedestrians is improved when refuge islands are present. Even though there is limited evidence, it seems as if refuges, especially on streets having more than two lanes, are beneficial for pedestrians from a safety point of view. [Zegeer et al. \(2005\)](#) found that when a refuge island is installed at an existing crosswalk on a road with more than two lanes the number of pedestrian crashes drops significantly and by an estimated average of 44%. The result is controlled for both vehicular and pedestrian volumes. Another study claims that “on a road where pedestrians often cross without a crossing facility, a refuge will decrease pedestrian accidents by around 40%.”

Crossing, at locations with refuge islands, is the safest on roads with low to medium flows of vehicle traffic, and where speeds are below 50 km/h (30 mph) but they certainly help pedestrians find safer gaps at high-speed, high-volume streets as well.

One reason why islands contribute to higher safety may be speed reductions. Pedestrian refuges slow traffic because they narrow the road, and may remind drivers that pedestrians could be crossing the road. One study showed that vehicle speed at pedestrian refuges was reduced by 6%. However, this speed reduction varies with the width of the opening between the sidewalk curb and the refuge curb. If the width is 4 m or more, there is probably very little effect on speed. If the opening is 2.1 m, as used at at least a few locations in London, the resulting speed is barely crawl speed. If going to such extremes, the opening on the other side of the refuge island will need to be kept wider to allow trucks and emergency vehicles to get by the island using the wrong side of the street traveling in the opposing traffic direction.

Another reason for safety improvements may be that there might be a change in pedestrian behavior. [Lee and Abdel-Aty \(2005\)](#) showed that at crosswalks (with or without signalization) at intersections, there were 36% fewer (–45; –26) pedestrian accidents where the pedestrian was considered guilty when the main road has a median compared to when it does not.

It should be noted that pedestrian refuge island could be used both at marked crosswalks and at unmarked crossing points. Especially where speeds are high, marking crosswalks may not be safe, but refuge islands may be the most needed at such location.

To sum up, the main advantages with a median island at pedestrian crossing points are:

- Allows pedestrians to cross more easily than if there was no island.
- May help pedestrians to cross the road more quickly, as a gap is only required in one direction of traffic at a time.
- Pedestrian refuges narrow the road, which may reduce the speed of vehicles.

The main disadvantages seem to be:

- For the pedestrian to cross safely, they must have good judgment of motor vehicle speeds and gaps in vehicle traffic.
- Visually impaired people, or those with other disabilities, may find refuge island less easy to use.
- Some motor vehicle drivers act dangerously near crossing islands if a cyclist is passing through. They may squeeze past the cyclist when passing the crossing island, or swerve dangerously around the cyclist just before the crossing island. Cyclists can feel very uncomfortable with this behavior.
- In areas with heavy snowfall, island makes it harder to remove snow.

Restrictions are as follows:

- Refuge islands must be wide enough in order to accommodate baby carriages and wheelchairs with a person behind it, a minimum of 1.2 m, and the raised areas should be on both sides of a walk area that should be at the same level as the rest of the crossing.
- Normally, road widths must be at least 3.5 m on either side of the refuge. This gives a minimum curb-to-curb street width of 8.2 m. That width has to be increased if the location is on a bend, expects oversized motor vehicles, or has bicycle traffic in the travel lane and motor-vehicle speeds are so high that bicyclists cannot comfortably claim the entire lane. Widths may also need to be increased if the municipality uses snowplows that cannot accommodate 3.5-m widths.
- Parking restrictions may need to be imposed on approaches near to the refuge, though if street width allows it, using bulb-outs means that parking can be allowed close to the crossing point.

A refuge island is also used to regulate the position of motorized traffic. For instance, traffic islands can be used at partially blind intersections on backstreets to prevent cars from cutting a corner with potentially dangerous results, or to totally prevent some movements, for traffic safety or traffic calming reasons.

Traffic Medians

When traffic islands are longer, they are instead typically called traffic medians, or median islands: a strip in the middle of a road that separates opposing lanes. In urban or suburban areas, where pedestrians are permitted, traffic medians have the same mission as refuge islands in making it easier and safer for pedestrians to cross busy and wide roads, often congested with motorized traffic. On two-lane streets, they also prohibit drivers from passing slower vehicles, reducing speed and a danger to pedestrians of being hit by a car passing another one.

The [Federal Highway Administration \(2019\)](#) has summed up the effects for pedestrians in the following way.

Providing raised medians or pedestrian refuge areas at pedestrian crossings at marked crosswalks has demonstrated a 46% reduction in pedestrian crashes. At unmarked crosswalk locations, pedestrian crashes have been reduced by 39%. Installing raised pedestrian refuge islands on the approaches to non-signalized intersections has had the most impact in reducing pedestrian crashes.

One benefit of medians is that they also provide a space to install improved lighting at pedestrian crossing locations. Improved lighting has been shown to reduce nighttime pedestrian fatalities at crossings by 78%.

Once being away from urban and suburban areas, the aim of the median strip is primarily to increase the distance between the two driving directions in order to mitigate the risk that drivers unintentionally enter the wrong side of the road and have head-on collisions. The *median strip* or *central reservation* (which on some roads may allow traffic at openings making turns) is the reserved area that separates the opposing lanes of traffic on divided roadways, such as divided highways, dual carriageways, freeways, and motorways.

Separating traffic directions is a very important aim: in the United States it has been found that roadway or lane departure crashes account for well over half of all fatal roadway crashes. The situation in Europe is more or less the same. This includes vehicles crossing the centerline and either sideswiping or striking the front end of opposing vehicles. Therefore, big efforts are made in order to mitigate this problem. The most obvious measure is to prevent vehicles physically from passing the middle of the road. However, the question is how exactly should that be done?

The reserved area in the center of the road may be paved but it is commonly adapted to other functions; for example, it may accommodate decorative landscaping, trees, or some kind of light rail or railway.

Median barriers are of course the most potential way of preventing cars from entering the wrong side of the road. It is, therefore, presented separately in the next section. However, there are several options that are used without a median barrier, and those are presented first.

The area is quite complex, however, with lots of different kinds of measures, in different context. Therefore, there are not a great number of comprehensive results regarding the effects of medians. However, the Transport Economics Institute in Oslo, Norway, has produced a meta-analysis based on approximately 40 studies (https://tsh.toi.no/index.html?146863#anchor_1468639). They are based on before–after studies with control, as well as studies with and without medians, which are controlled for various confounding variables, as well as for any important publication bias, or any regression-to-the-mean effects. It has been found that newer studies indicate a more positive effect than older ones. In most cases, where it has been possible, the results shown are, therefore, from the year 2000 or later. The studies include crashes with fatalities or crashes with unspecified severity. Later, follows the findings of the analysis of median strips with curbstones but without guardrail based on before–after studies.

Median strip on segment between intersections: The establishing of a median strip with curbstones at stretches between intersections seems to reduce the number of injury crashes, but not the number of property damage only crashes. The effect is largest on the most severe crashes. The result seems independent on what type of study it is and how old it is, and it also seems to be independent of publication bias.

The reason why a median strip seems to have larger impact on more severe crashes is probably that the median strip changes the distribution of different types of crashes, as well as the severity distribution of the crashes. Gabler et al. (2005) showed that installing a median strip reduces the number of head-on collisions but increases crashes of less severity. Another study, by Saito et al. (2005), showed that the number of side-impact collisions was reduced while there were more rear-end crashes. Normally, side collisions are more severe than rear-end crashes. In a study from New Zealand it was found that there were 75% fewer head-on collisions and a lower percentage of fatal crashes (7.2% without and 2.8% with median strip) and crashes with severe injuries (21.2% without and 16.6% with median strip) on roads with median strips.

Median Strip at Intersections

These results refer to intersections between roads with versus without median strips and are valid for intersections where at least one of the intersecting roads has a median strip (median strip for channelization is not included). At intersections, the results show that median strip with curb increases the number of crashes, mostly in rural areas. The results are not statistically significant but show the same results as median strip versus two-way left turn lanes, that is, a median strip has less favorable effect at intersections compared with segments between intersections. The explanation may be that intersections with median strips are bigger and less perspicuous compared with intersections without a median strip. Besides, a median strip is an obstacle that may cause crashes by itself.

Median Strip Instead of Two-Way Left Turn Lanes

Altogether, there was a 24% reduction of all accidents when replacing two-way left turn lanes with a continuous raised median. An even larger reduction was found for crashes between intersections. However, at intersections crashes increased by 50%. The results indicate that the effect of a median strip is larger for segments between intersections compared with at intersections. The effect is probably largest for pedestrian crashes.

The Width of the Median Strip

Roads with wider median strips have fewer crashes than roads with narrower strips. On segments between intersections, however, the effect is quite small, even though statistically significant. At intersections, the effect is larger but not statistically significant. The fact that an increase of the width of the median strip would result in a larger effect at intersections was not expected based on the

results from the studies of roads with versus without median strips, because in these cases the median strip was found to have a crash reduction only along the segments between intersections, not at intersections. There is obviously a need for further research of this. One possible explanation is that the wide median makes the intersection appear as two separate intersections with one-way streets, reducing complexity for drivers, whereas a narrow refuge island does not give the driver enough time to navigate out of the first before they have entered the second.

Type of Median Strip

Quite a few studies have been dealing with different types of medians. All in all, the results indicate that both painted and lowered median may have a somewhat better effect than a median with curbstones. The reason for this is unknown, but may have to do with more hits of curbstones. In general, hitting a curbstone at high speed may result in a driver losing control of their vehicle, and curbstones should probably not be used at roads with allowed speeds above 70 km/h.

Effect on Mobility

At side roads or at intersections a median prevents cars from making left turns if the design is such that crossings are not possible. In that case, roundabouts should be used to allow U-turns at strategic locations. It has been found that the effect of medians is:

- Reducing motor vehicle crashes by 15%.
- Decreasing delays (>30%) for motorists.
- Increasing capacity (>30%) of roadways.
- Reducing vehicle speeds on the roadway.
- Providing space for landscaping within the right-of-way.
- Providing space to install additional roadway lighting, further improving the safety of the roadway.
- Providing space to allow for supplemental signage on multilane roadways.
- Costing less to build and maintain if unpaved than paved medians.
- The Federal Highway Administration (FHWA) strongly encourages the use of raised medians (or refuge areas) in curbed sections of multilane roadways in urban and suburban areas, particularly in areas where there are mixtures of a significant number of pedestrians, high volumes of traffic (more than 12,000 vehicles per day), and intermediate- or high-travel speeds.
- FHWA guidance further states that medians/refuge islands should be at least 4 feet (1.2 m) wide (preferably 8 feet (2.4 m) wide for accommodation of pedestrian comfort and safety) and of adequate length to allow the anticipated number of pedestrians to stand and wait for gaps in traffic before crossing the second half of the street.
- On refuges 6 feet (1.8 m) or wider that serve designated pedestrian crossings, detectable warning strips complying with the requirements of the Americans with Disabilities Act must be installed.
- Medians are especially important at transit stop locations. Transit stops are frequently located along busy arterials at uncontrolled crossing locations. Providing medians can make these crossings safer and more appealing to existing and potential transit users. If transit stops do not have bus turnouts but rather bulb-outs narrowing the roadway, a refuge island will prohibit drivers from passing a stopped bus which will improve not just safety but also mobility for transit users since there will be fewer cars in front of the bus once it starts up.

The Ultimate Measure: Medians With Guardrails

A guardrail in the middle of the road has the option of preventing and even eliminating vehicles from entering the wrong side of the road. However, there is a difference between theory and practice. Different types of barriers are used and implemented differently in different types of context. The main types of barriers used are: concrete barriers, steel barriers, or beam guardrails. The safety effect of guardrails by themselves is discussed in a different article of this encyclopedia, but later follows some safety results as well for guardrails placed in medians.

Following are results presented from a meta-analysis made by Transport Economics in Oslo, Norway (<https://tsh.toi.no/index.html?21836>). It is based on almost 50 different studies. The most important findings are that guardrails—any type—reduce fatalities for all types of crashes by about 15% (−33; +7). Most effective seems to be concrete barriers in the median strip on a multilane road, 38% (−69; +24) reduction, while a steel barrier in the median strip on a multilane road results in 12% (−32; +13) reduction only. Both results are nonsignificant though. There are no results presented for fatal injuries together with beam guardrails. For all crashes together with unspecified seriousness, however, there are results for all three types of rails. Generally, the reductions are much smaller than for fatalities: of crashes with unspecified seriousness for all types of guardrails the reduction is 8% (−26; +2), for concrete barriers in the median strip on a multilane road there is a reduction of 13% (−46; +40), for steel barriers in the median strip on a multilane road there is a reduction of 4% (−27; +27), and for beam guardrails the reduction is 7% (−19; +7).

These results indicate that concrete barriers are more effective in preventing serious crashes, while the difference between steel and cable barriers is small. At the same time, there are studies indicating that a resilient barrier produces fewer crashes than a non-resilient barrier. One study even found that concrete barriers produced higher risk for serious injuries than steel barriers, even though it did not compensate for the lower risk due to vehicles coming over on the wrong side.

Most results indicate that a guardrail that is less resilient is more efficient in preventing vehicles from entering the wrong side of the road. It is found that vehicles crossing the median are fewer when the guardrail is made of concrete. The results, however, are not very clear. However, resilient rails are not as efficient in preventing vehicles to enter the wrong side of the road, at the same time as the consequences of those crashes that occur is more serious. For motorcycle riders, the risk of being killed is increasing when hitting a barrier, hitting a concrete barrier being the worst case.

The crash type that is mostly reduced on roads with guardrails is crashes where the vehicle is crossing the median. Other crashes where the median is not crossed increase in numbers; crashes with unspecified seriousness have increased in the meta-analysis by 73%. The main reason is that vehicles are hitting the guardrail, and stay on that side of the road, so a potential—and more serious—crash on the other side of the median had been avoided. Other types of crashes do not seem to be changed.

Generally, it must be said that most results in the meta-analysis are not statistically reliable. Additional analyses indicate that there are real differences between outcome with regard to different injury classes and between different crash types. The differences between different rail types are, however, not statistically reliable. The differences found may therefore not be real. This can even apply to the results for different types of guardrail, both results where a direct comparison between different types of rails has been made and other studies have shown that more resilient rails have a more positive effect than less resilient ones.

Less Expensive but Still Effective: Centerline Rumble Strips

The safety effect of rumble strips, both continuous shoulder and centerline rumble strips, are addressed in a separate article of the encyclopedia, but since centerline rumble strips are a type of non-raised narrow median, they are also included here, from a slightly different perspective.

Rural two-lane roads generally lack physical measures such as wide medians or barriers to separate opposing traffic flows. Or, even if there is space enough, the cost may be too high to install it. One option then is to install rumble strips in the centerline. These strips and stripes are designed to address crashes caused by distracted, drowsy, or otherwise inattentive drivers who drift from their side of the road. With respect to fatal head-on crashes on rural two-lane roads, it has been found in studies of several jurisdictions that roughly half are caused by inattentiveness or drowsiness, and the other half by losing control and crossing the centerline because of too high speed. Only a few percent of head-on fatalities are caused by people crossing the median on purpose to pass another vehicle. In other words, continuous rumble strips should be able to affect about half of all serious head-on crashes.

Centerline rumble strips are one of the many infrastructure-related measures applied to prevent the occurrence of car accidents, especially crossover, run-off-the-road, and head-on accidents. Quite a few studies have been carried out, in different countries. There is a meta-analysis made at Transport Economics Institute in Oslo based on almost 20 studies (https://tsh.toi.no/325-forsterket-kantoppmerking.htm#anchor_136975-90). It shows that there was a 10% reduction of all crashes and as much as a 37% reduction of the target behaviors (head-on and side-impact collisions at left side and leaving the road to the left side). Both reductions are statistically significant, and similar for different degrees of severity. All studies were made on two-lane roads in non-built-up areas. The main reason for reductions seems to be either that drivers are alerted when they hit the strips, or that they are driving with somewhat longer distances to the strips (which is good but potentially could have negative effects on bicycle safety on roads lacking bicycle tracks and wide shoulders). Generally, it was not found that speeds were changed. Two studies found that nighttime speeds were lower, but that has not been confirmed in other studies.

Centerline rumble strips have been installed on many of the Danish rural roads in the last decade. As previous studies on the effectiveness of this measure were not conducted in Denmark, and many roads have centerline rumble strips installed, it was deemed necessary to implement an appropriate study. This study investigated whether centerline rumble strips really work. By using previously recorded accidents data and traffic volumes from the Road Directorate, the study evaluated the effectiveness of safety improvement on each site as well as the overall safety program. Meta-analysis method was applied to 35 sites from locations all over the country. The evaluation result complied with those from the international studies. The total number of accidents was reduced by 20% following the installations of the centerline rumble strips.

A US study presents similar conclusions. Opposing-direction crashes account for about 20% of all fatal crashes on rural two-lane roads and result in about 4500 fatalities annually in the United States. An empirical Bayes before–after procedure was employed to properly account for regression to the mean while normalizing for differences in traffic volume and other factors between the before and after periods. Overall results indicated significant reductions for all injury crashes combined (14%, 95% confidence interval (95% CI) = 5%–23%) as well as for frontal and opposing-direction sideswipe injury crashes (25%, 95% CI = 6%–44%)—the primary target of centerline rumble strips. The authors summarize: in light of their effectiveness and relatively low installation costs, consideration should be given to installing centerline rumble strips more widely on rural two-lane roads to reduce the risk of frontal and opposing-direction sideswipe crashes. The US FHWA describes Centerline Rumble Strips as a “Proven Safety Countermeasure,” with a 44%–64% reduction of head-on, opposite-direction, and sideswipe fatal and injury crashes.

Median Barrier on 13-m Wide Roads

Deaths on rural roads are a serious road safety problem. Due to the risks imposed by high speeds, multifunctionality, lower infrastructure safety, and mix of different road users, rural roads are often dangerous roads with relatively high risk levels compared to motorways. In Sweden, a special road safety concern during the 1990s was the large number of fatal and serious crashes on rural

13-m wide two-lane roads. These 13-m roads had two travel lanes and shoulders that were about 3-m wide. And, in Sweden, it is legal to enter the shoulder when driving a farm tractor or other vehicle at low speed to let faster vehicles pass. By the 1980s, a culture had developed that people going close to the speed limit often entered the shoulder to allow faster vehicles to pass. Then, faster drivers started to expect everybody to do that when passed, and if people did not move over, some drivers would cross the centerline assuming oncoming traffic would enter their shoulder, sometimes resulting in serious crashes. In 1997, the Swedish Parliament adopted the so-called Vision Zero (see separate article in this encyclopedia), a vision that nobody should be killed or seriously injured on Swedish roads. One main solution proved to be a redesign of the 13-m wide roads to 2 + 1 lanes with a median barrier. Starting in 2009, this solution was also applied on rural roads with road width of about 9–10 m. A 2 + 1 road with median barrier has a continuous three-lane cross-section with alternating passing lanes to allow defined sections of overtaking, the two directions of travel separated by a flush divider with a median barrier. The barrier is in Sweden a cable barrier. Comparing 13-m wide, 2 + 1 roads with narrow 2 + 1 roads (9 m), the main difference is the length and frequency of passing lanes. For narrow 2 + 1 roads, the share of passing lanes varies between 15% and 30% compared to about 40% for the 13-m roads. (The reason the wider roads with continuous three lanes do not give 50% passing opportunities is that the transition from two lanes to one lane needs a safety zone when no one can use the middle lane, where the cable barrier moves from one side to the other.)

The safety effect of 2 + 1 roads, 13-m wide in Sweden, has been extensively assessed. Compared with normal 13-m wide roads there is a reduction of the number of killed by more than 75%, independent of whether the speed limit is 90 km/h or 100 km/h. The effect on killed and seriously injured is between 50% and 60%, highest for a speed limit of 90 km/h, while for injury crashes there is a much smaller effect and only on 90 km/h roads, minus 13%. The result of this is that Sweden recently has stopped using the almost “universal” speed limit of 90 km/h on 13-m roads and now use 80 km/h on two-lane roads without center barriers and 100 km/h on roads with center barrier. (A few 13-m roads that have grade separated interchanges only have maintained 110 km/h.) The safety is thereby increased on both the roads with and without center barriers, compared to the traditional design with 90 km/h limit, and mobility improved on the ones with cable barriers and is reduced on the ones where the speed limit was lowered.

Crashes with the guardrail are quite frequent but less severe. On average, there are two hits per kilometer and year. This involves of course costs for repairing.

Motorcycle riders have been quite negative to the cable wires in Sweden. However, the result is a reduction of serious and fatal crashes by 40%–50% for motorcyclists. This result contradicts the earlier result built on a meta-analysis. The reason for the difference is most probably that in the meta-analysis the barrier that was used was primarily concrete barriers, while in the 2 + 1 road case cable barriers were used.

Regarding mobility, it was found that the average speed went up by 2 km/h on roads with 90 km/h speed limit (increase in the direction that went to two lanes) while it was unchanged for roads with 110 km/h speed limit. It was also found that capacity is around 1600–1700 motor vehicles per hour measured during a 15-min period, which is 300 vehicles—15%—less compared with a normal 13-m wide road.

A special evaluation of the safety effects of narrow 2 + 1 roads in Sweden has also been made. Those roads had narrow shoulders, in the before period and did not allow four informal lanes of traffic, which the 13-m two-lane roads did and therefore had different safety issues in the before period. Results from a before and after study show a number of significant effects; the total number of fatalities and seriously injured decreased by 50% and the total number of personal injury crashes decreased by 21%. Looking only at links (excluding intersections), the number of fatalities and seriously injured decreased by 63% and the personal injury crashes by 28%. For almost all of the included road sections, the speed limit was also raised from 90 km/h to 100 km/h when the road was rebuilt to 2 + 1. Regarding mobility there was no difference in efficiency compared to earlier evaluations of traditional 2 + 1 roads with 100 km/h and 40% passing lanes can be observed.

There are some special complications that have to be carefully discussed and treated: the first point is how emergency vehicles are accommodated on one-lane stretches and the second one is the risk of cars breaking down on one lane stretches. The third one is how maintenance work is done. The fourth one is the restricted access of property owners, and the fifth is public perception. In Sweden, there have also been a lot of discussions around the fact that pedestrians and bicycle riders are prohibited on these kinds of roads. In the south of Sweden, where biking is quite common, the authorities have built a bike road parallel to the 2 + 1 road. This, of course, makes the cost of reconstruction of the road considerably higher. And, in areas with little bicycle traffic, such parallel bicycle paths may not be built adding considerable distance for bicycling to certain destinations.

Although in smaller scale than in Sweden, there are 2 + 1 roads also in Ireland, Norway, Germany, and Finland. In Ireland cable barrier is used as in Sweden, while in Norway a concrete barrier is used. In both cases the effects are similar to the ones in Sweden. In Germany and Finland, the 2 + 1 roads are done by restriping wider roads. The effect is, therefore, considerably smaller than in Sweden.

Biography

Christer Hydén has been active in the traffic safety field for around 40 years. His first achievement was the development of a Traffic Conflict Technique, a way of assessing risk on the roads with the help of near accidents. He was the President of ICTCT (at first standing for “International Co-operation in Traffic Conflicts Techniques” and later for “International Co-operation on Theories and Concepts in Traffic Safety”) from 1977 to 2011. One other field of expertise is the impact of speed, and the effect of different measures, like Traffic Calming and Speed Limiters in vehicles. He is a member of the Independent Council for Road Safety International (ICORSI).

Perceived Risk and Objective Risk

Risk is the probability and magnitude of harm, such as the probability and consequences of getting into an accident when driving a car. However, peoples' judgments of risks often deviate from actual probabilities of harm; as a consequence, we need to differentiate between *perceived risks* and *objective risks*. Objective risks are measurable and require analytical processing of facts such as the number of fatalities by miles driven per year. Perceived risks are based on subjective estimates for the likelihood of harm. Risk perception has been defined in various ways, including the subjective assessment of risk and the level of concern associated with the consequences (Sjöberg et al., 2004) or beliefs, attitudes, judgments, feelings and values associated with a risk (Pidgeon et al., 1992). Some social scientists argue that risk assessment is inherently subjective, because it always includes components of subjective judgment such as selection and interpretation of data and deciding the consequences. An engineer's risk estimate may be based on theoretical models, but the model is driven by assumptions and individual judgment. The subjectivity of risk assessment is also demonstrated, for example, by the choice of a measure for traffic mortality risks. Mortality risks could be expressed by deaths per mile driven or by deaths per million cars. As a result, although danger is real, the assessment of risk may never be purely objective (Slovic, 2016).

Risk means different things to different people. Assessing risks based on probabilities of harm requires cognitive analysis, which is one way that humans process information about risk. Another more common way is reliance on intuition, affective reactions, and feelings, which is quicker, easier and often more efficient than reliance on cognitive analysis (Slovic and Peters, 2006). From an evolutionary perspective, being able to quickly and automatically react to danger is essential for survival. However, while intuition leads to good decisions in most cases, it can sometimes lead people astray. This explains why risk assessments of experts and laypeople often differ. While experts (e.g., risk analysts) use cognitive analysis and rely on statistics, laypeople (e.g., consumers) are sensitive to more emotional factors such as catastrophic potential or controllability. For example, after the terrorist attacks in the United States on September 11, 2001, many Americans dreaded flying and decided to drive instead. As a result, traffic fatalities increased in the three months following the attack. In fact, the data suggest that more Americans died on the road by avoiding flying in the aftermath of the attack than the total number of passengers killed on the four flights that were attacked (Gigerenzer, 2004). This example demonstrates that people's perceptions of risk are more sensitive to the possibility of outcomes that carry strong emotional responses rather than probabilities. Because people focus so much on the negative outcome, they are less attentive to the small probability of occurrence (Loewenstein et al., 2001; Rottenstreich and Hsee, 2001; Sunstein, 2003).

In their psychometric paradigm, Fischhoff et al. (1978) demonstrated the multidimensionality of risk perception by distilling several characteristics of hazards that influence subjective risk estimates among laypeople. These characteristics include voluntariness of exposure, control over the risk, immediacy of consequences, familiarity with and knowledge about the hazard, the hazard's catastrophic potential, its dreadfulness, the severity of its consequences, and to what extent the hazard is known to science. Most of these characteristics were shown to highly correlate (e.g., risks that are rated as voluntary are often also perceived as controllable) and could be narrowed down to two main dimensions: dread risk and unknown risk (or novelty). Dread risk is characterized by lack of control, catastrophic potential and fatal consequences associated with an activity or event, while unknown risks are characterized by being unfamiliar, unobservable, poorly understood by science, and delayed in their consequences. Driving is a voluntary and familiar experience, which is often perceived as controllable. As a result, risk perception is reduced, which may at least in part explain why drivers were long reluctant to wear a seatbelt (Slovic et al., 1978) and why many do not refrain from texting while driving.

Further, studies have indicated that dread risk is a stronger predictor for people's risk perceptions than unknown risk (Slovic, 1987). As a result, people especially avoid risks that are fatal to many people at once. A hazard that may cause the same amount of fatalities over a longer period is thus less dreaded. This explains why many people generally fear flying more than driving, although from a statistical perspective, taking the car to the airport is the most dangerous part of the trip. Dread risks are perceived as less controllable, and people often have little knowledge about their actual probabilities. Additionally, dread risks that have the potential to kill many people at once may be a substantial threat to the society (Galesic and Garcia-Retamero, 2012).

Humans are driven by a need for safety, control, and predictability (van den Bos, 2009). Because the world rarely offers complete certainty, humans depend on often unconscious strategies that increase their perceptions of safety and decrease their perceptions of risk. For example, while people make quite accurate judgments about societal traffic risks (Lichtenstein et al., 1978), many do not feel that these risks apply to them personally. Most people underestimate personal risks (e.g., due to perceived control) and believe that they are safer drivers than the average driver (Svenson, 1981). One study found that after only one year of driving practice, most drivers overestimate their technical skill (e.g., reaction times, driving on slippery roads) and after three years they consider themselves above average in general driving skills (Svenson et al., 1985). These results have not been without critique, however, as data analysis has indicated that most drivers actually have few accidents while few have many accidents, and therefore most drivers are safer than the arithmetic mean (Gigerenzer et al., 2012). In addition, most people think they are less vulnerable than other people and that others are more likely to be affected by harm, which has been termed *unrealistic optimism* or *optimism bias* (Weinstein, 1980). Unrealistic optimism is associated with feelings of control over the driving situation. People acquire feelings of control over driving situations, in part, through driving experience regardless of whether they have experienced accidents or not (Svenson et al., 1985).

Risk Judgments

Bounded Rationality and the Affect Heuristic

Driving situations are complex, as various pieces of information must be considered when making judgments behind the wheel. These pieces of information include one's own speed, road and weather conditions, or predictions about another driver's behavior. In addition to these considerations, judgments and decisions in driving situations often have to be made under time pressure. However, the human mind is not able to consciously consider all the information that is relevant in a given situation, especially when under time pressure, which has been termed *bounded rationality* (Simon, 1955). Throughout their evolutionary history, humans have survived by relying on their intuition and quickly responding to threats in terms of fight-or-flight. In a driving situation, quick reactions such as braking or swerving happen without having calculated the time it takes to approach the car in front of us. Relying on intuition and feelings is often useful in situations that require quick decision making, but sometimes feelings can also get in the way. In a study on driving behavior, participants with neurological impairments who lacked emotional reactions stayed calm when hitting ice on the road, while healthy participants were more likely to panic and slam the brakes, which caused the car to skid out of control (Shiv et al., 2005).

In order to make complex decisions under time pressure, humans often rely on mental shortcuts, also termed *heuristics*, that simplify decisions, but maintain a sufficient level of accuracy (Raue and Scholl, 2018; Tversky and Kahneman, 1974). Relying on affect (i.e., good or bad feelings) to make judgments about risks is one way to simplify a complex situation and has been labeled the *affect heuristic*. Although the analysis of risks is important for decision making, relying on feelings is quicker, easier, and often more efficient (Slovic, 2016). In fact, rational decision making is generally preceded by feelings and seems to depend on prior emotional processing (Bechara and Damasio, 2005; Zajonc, 1980). According to the affect heuristic, affect that is associated with a hazard serves as a cue for the perceived likelihood of harm. Voluntary activities such as driving are often associated with positive affect—that is, it feels good to do them—which decreases risk perceptions associated with the activity. However, negative personal experiences or fear-evoking media reports may increase risk perception. For example, in the rare event of an airplane accident, the media reports extensively about it, often by using affect-laden images. In addition to the emotional reactions these reports create, media attention also makes the event easier to come to mind in the aftermath, which is an example of the *availability heuristic* (Tversky and Kahneman, 1974). People use the availability heuristic to make judgments about frequencies or probabilities; an event that comes easily to mind makes it seem more likely. Usually, more frequent events come to mind more easily, but people's perceptions about the frequency of occurrence can be biased due to, for example, vivid media coverage (Combs and Slovic, 1979).

The affect heuristic has especially been studied in the area of technology acceptance. In these studies, it was found that perceived risk and perceived benefits associated with a technology are inversely related. In general, highly risky technologies are only used if they are also highly beneficial, but in most people's minds perceived risk declines with an increase in perceived benefit and vice versa. This relationship could be explained by the affect heuristic as positive affect results in lower risk and higher benefit perception, while negative affect results in higher risk and lower benefit perceptions. This inverse relationship between risk and benefit perceptions increases under time pressure, which further supports the affect heuristic by indicating that people's judgments are not based on cognitive analysis (Finucane et al., 2000; Slovic and Peters, 2006). Recent research has suggested that affect associated with a known technology, such as traditional driving, may even inform people's risk perceptions of a new, but similar, technology such as self-driving cars (Raue et al., 2019).

Risk as Feelings and Perceived Control

Another approach is the risk-as-feelings hypothesis, which focuses on the behavioral consequences of feelings associated with risks (Loewenstein et al., 2001). Negative feelings associated with flying (e.g., due to negative experiences or intensive media coverage of very rare negative events) may prevent some people from traveling by airplane although most people *know* that flying is safe. Education about airplane safety, however, often does little to change the behavior of an anxious flyer. In fact, people's judgments about the safety of commercial aviation are quite accurate when compared with accident statistics (Slovic et al., 1979). Despite the knowledge that air travel is very safe, many feel anxious about flying. In an airplane, passengers have no control (not even an illusion of control as many people perceive when driving a car) and cannot see the actions of the pilot. Being in an airplane is an unfamiliar situation for many and most people usually have only a vague idea of how airplanes work. And while accidents with airplanes are extremely rare, consequences of accidents are almost always fatal and catastrophic as many people die in one single incident (Mauro, 2019).

Recent research has also suggested that giving up control may be a major barrier to the adoption of self-driving cars (Raue et al., 2019). The self-driving car will affect the future of transportation, but research has indicated that the public perceives the technology as riskier than conventional driving, which may hinder adoption (Brell et al., 2018; König and Neumayr, 2017; Ward et al., 2017). Having to give up control, as well as lack of familiarity, poor understanding of how the technology works, lack of trust, and unresolved ethical issues (Meder et al., 2018; Visschers and Siegrist, 2018) may explain some of the skepticism associated with self-driving cars. People initially also viewed the conventional car with skepticism, but it ultimately earned their trust and acceptance (Ladd, 2008). In fact, people's attitudes and perceptions might be more of a barrier to a successful introduction of self-driving cars than technical challenges (Coughlin et al., 2019). Experience with automated vehicle technologies already on the market has been associated with a decrease in risk perceptions associated with self-driving cars (Brell et al., 2018; Raue et al., 2019).

Risk Perception and Risk Behavior

Risk perception and risk behavior are generally negatively correlated: the higher one perceives the risk of a behavior the less likely the person will engage in that behavior (Ferrer and Klein, 2015; Mills et al., 2007). However, despite having been educated about certain risks (e.g., drinking and driving, texting and driving) and showing less unrealistic optimism (Fischhoff et al., 2010; Quadrel et al., 1993), adolescents tend to engage in more risky driving behavior than older and more experienced drivers (Gershon et al., 2018). For example, adolescents are more likely to engage in secondary tasks such as mobile phone usage or reaching for objects, which takes their eyes off the road and increases their crash risk (Gershon et al., 2019). Explanations for risky driving behavior among adolescents include lack of driving experience and high susceptibility to peer influence (Gershon et al., 2018; Frey et al., 2016). Social interactions strongly influence adolescents in various contexts and peer presence has been shown to increase their risk-taking behavior in driving simulators (Steinberg, 2008). Increased risk-taking behavior might result from adolescents' preference for trading off risks and rewards, thus, putting more weight on the benefits (e.g., peer acceptance) than the risk (Reyna et al., 2015).

Mobile Phone Use While Driving

In 2017, 9% of fatalities in motor vehicle crashes involved distracted drivers and 14% of these distractions were caused by mobile phone use (National Highway Safety Administration, 2019). Nevertheless, in a recent study conducted in Germany (Lemster and Lerner, 2019), 52% of the participants admitted using their mobile phones at least occasionally when driving. In a study with college students, 91% indicated that they occasionally text while driving despite agreeing that this behavior was dangerous (Harrison, 2011). Perceptions of being in control of the situation, mobile phone dependence and attachment, propensity for risk-taking, and impulsivity have been shown to contribute to people's use of mobile phones while driving (Beck and Watters, 2016; Weller et al., 2013). In addition, compensatory beliefs such that negative effects of risky behavior can be reduced or eliminated by showing safe behavior (e.g., using the mobile phone after having slowed down) contribute to risky behavior as well (Zhou et al., 2016). Although slowing down may decrease the actual risk of using a mobile phone while driving, it is still a distraction that may result in an accident. Specifically, among adolescents, predictors for using mobile phones while driving further include social influences such as the fear of missing out or the fear of being perceived as rude or impolite if not responding to a message immediately (Lemster and Lerner, 2019; Martha and Griffet, 2007).

Learned Carelessness

Research suggests that decreased risk perception can also be explained by repeated risky behavior without negative consequences, which results in learned carelessness (Frey et al., 2016; Raue and Schneider, 2019). According to the *theory of learned carelessness*, learning experiences based on positive consequences of behavior that are due to luck, coincidence or repeated risky behavior without negative consequences may lead to biased perceptions of risk (Frey and Schulz-Hardt, 1997). For example, if speeding or driving under the influence of alcohol has never resulted in an accident or legal consequences, a person is likely to continue the behavior and might increase their speed even more or have another beer before getting into the car. The absence of any negative experience can

lead to habituation and a biased perception of an actual risk and, consequently, to learned carelessness. Routine procedures with no encounters of critical incidents after many repetitions are especially prone to developing learned carelessness. In aviation, for example, checklists are used to ensure all precautionary measures are taken and to prevent human error. In an experimental study, airline pilots who repeatedly encountered errors while going through their flight plans were more likely to detect errors in the future than those who never encountered errors. However, no differences were found in their performance of flight inspections (Aust et al., 2011). The theory of learned carelessness suggests that when things are going well, people tend to feel safe and secure and to assume that these conditions will continue, despite a potential increase in risk. This also reflects people's general insensitivity to risk accumulation over repeated exposure (Fischhoff, 2009). People sometimes adjust their behavior to match their biased sense of safety (e.g., increasing speed, engaging in critical shortcuts in routine safety procedures) rather than adapting it to the actual risk. However, more research is needed to further validate the theory of learned carelessness.

Risk Homeostasis and Risk Compensation

One explanation for this matching process is based on risk homeostasis theory (Lermer et al., 2016; Wilde, 1982), also known as risk compensation hypothesis (Wilde, 2002). This theory states that people have the tendency to show riskier behavior (e.g. risky driving) after a perceived increase in safety (e.g. installation of a specific safety system). It is assumed that each person has a certain individual level of risk that he or she is willing to tolerate. When external factors contribute to an increase in perceived safety, this safety gain is offset by an increase in risky behavior. This means that the safer people feel, the riskier their behavior becomes. For example, after the introduction of the antilock brake system in cars, the number of accidents did not fall as expected, but increased (e.g., Biehl et al., 1987). The increase in risky behavior is not limited to safety perceptions of oneself. For instance, a field study revealed that cyclists wearing helmets are overtaken by car drivers at a shorter distance than cyclists without helmets (Robinson, 1996). Another study showed that more accidents tend to occur on easily manageable bends than on unclear stretches of the road, which drivers subjectively consider to be more dangerous. Drivers on clearly arranged routes chose significantly higher speeds (Petermann et al., 2008). However, it should be noted that the risk homeostasis theory is often controversially discussed. One counterargument is that the theory has not been supported in observations of seatbelt use among drivers (Evans et al., 1982) nor for bicycle helmet use among bicyclists. Most studies actually found that helmet use was associated with safer cycling behavior (Esmailikia et al., 2019).

While behavior may change occasionally as a result of a perceived change in risk, critiques argue that empirical evidence for risk homeostasis is still limited (Robertson and Pless, 2002). Although complete risk compensation as predicted by risk homeostasis theory lacks empirical support, there is evidence for behavioral adaption to some traffic safety measures. However, the effects and magnitude of such partial risk compensation behavior vary and not every safety measure is necessarily compensated. Because the effects of safety measures on risk behavior can rarely be studied in controlled experimental conditions, accurately capturing the multidimensionality of risk is difficult and may impede conclusive results on risk compensation (Adams, 1995; Evans, 1985; Hedlund, 2000). Various methodologies and forms of risk measurements, including self-reports, crash data, field, and laboratory studies may also explain conflicting results of studies on risk compensation (see Lermer et al., 2018 for a discussion on measuring subjective risk estimates).

Risk Communication

Most people generally struggle to understand statistical information, which is essential to make sense of risk statistics (Peters, 2012). Due to this lack of numeracy of the general public, their ability to make informed decisions based on the interpretation of statistical information about risk is limited. Because of this and their tendency to base their judgments on feelings rather than cognitive analyses, people are more susceptible to individual stories or vivid media reports than statistical information about risk, both of which can not only influence but also distort their perceptions and judgments. Therefore, alternative ways to communicate risks to the public have been suggested. In the health sector, for example, the use of visual aids has been successful in supporting people in understanding the risks and benefits of preventive screenings or medical procedures (Garcia-Retamero and Cokely, 2013). However, as shown earlier, even if people are aware of the risks associated with a behavior (e.g., texting and driving), they may not change their behavior due to unrealistic optimism, feeling in control of the situation, weighing risks and benefits and/or being influenced by their peers. Effective risk communication that not only addresses the way people perceive risk, but also acknowledges their social and psychological context is an important tool to increase personal relevance and ultimately change behavior (Bostrom et al., 2018). In the transportation sector, effective risk communication is essential on an individual and societal level. This includes preventing people from risky behavior such as speeding, texting while driving, or driving under the influence of alcohol, but also supporting them in making informed judgments about new technologies and encouraging proenvironmental behavior.

We thank Adam Felts for proofreading this chapter.

Biographies

Martina Raue is a Research Scientist at the MIT AgeLab in Cambridge, Massachusetts. She studies risk perception and decision making over the lifespan. Dr. Raue received her PhD in Social Psychology from the Ludwig-Maximilian University Munich in Germany and her Master's Degree in Psychology from the University of Basel in Switzerland.

Eva Lerner is a Professor for Business Psychology at the FOM University of Applied Sciences for Economics and Management in Munich, Germany, and Head of the Peer-to-Peer Mentoring Program at the Ludwig-Maximilian University Munich. Her research interests include risk behavior, decision making, and positive psychology. Dr. Lerner received her academic degrees from the University of Salzburg in Austria and the Ludwig-Maximilian University Munich in Germany.

Introduction

The objective of a road diet is to reduce excess lane capacity from roads that were overbuilt. The goal is improved safety, but there can also be operational benefits and other community benefits. The typical road diet conversion, at least in North America, is the reduction of a four-lane road (two-lanes in both directions) to two-travel lanes and a two-way left-turn lane (TWLTL) in the median. This has the benefit of making left-turns across the traffic stream easier and reduces blocking of traffic as vehicles wait to complete a left-turn. If the road diet occurs in an urban area, or rural area with pedestrian activity, the TWLTL may be interrupted with raised medians at every crosswalk. Average speeds in the travel lane are often reduced, as a lead vehicle will control the speed of following vehicles; weaving is also reduced. Drivers also perceive a narrower road, which reduces speeds (Burden and Lagerwey, 1999; Knapp et al., 2014).

The reduction in the number of traffic lanes allows pedestrians to more easily cross the road, as their exposure to moving traffic is less. Depending on the design, many road diets incorporate a bicycle lane or track or include a larger shoulder width that bicycles can use. There are safety benefits associated with bicycles having their own through-lane and this can improve vehicle flow as vehicles do not need to change lanes to pass a bicycle.

History of Road Diets

An obvious question is why are there so many roads with four lanes when fewer lanes could easily accommodate the traffic flow? In the United States, much of the expansion of the road network took place in an era of rapid growth in vehicle ownership and burgeoning budgets for highway development. Guidelines for roads with TWLTLs did not exist and most transportation agencies simply modified two-lane roads to four lanes, with no consideration of the impacts on communities.

While the earliest implementations of road diets can be traced back to the 1970s, these gained in popularity in the 1990s. This was largely due to advocates, such as Dan Burden, explaining the benefits to local communities throughout the country. More recently, the Federal Highway Administration (FHWA) has recognized that road diets can be effective as a safety countermeasure. While there have been some studies that have evaluated the crash reduction benefits, these are limited. In general, the guidance suggests that crash reductions ranging from 19% to 47% are feasible, depending on traffic volume and other details of the local area (Thomas, 2013). Many states and local communities are now developing policy and evaluating possible road diet conversions.

Typical Road Diet Configuration

The typical configuration for a road diet in North America is a road with two travel lanes and one two-way left-turn lane (TWLTL) in the middle of the road (Knapp et al., 2014). A schematic of this is shown in Fig. 1. Three examples of actual road diets are shown in Fig. 2 from three different locations. In these cases, the treatment of the shoulder varies. In panel-a there is a wide shoulder that can

Figure 1 Schematic of a typical road diet. *Source: FHWA.*

Figure 2 Typical road diet configurations. (A) Electric Ave, Lewiston, PA; (B) Grand River Ave., East Lansing, MI; (C) N 45th St., Seattle, WA. *Source: Google Maps.*

easily function as a bicycle lane; panel-b likewise has a shoulder, but not as wide as the example in panel-a. The last example shows a road diet in an urban setting; the shoulder is used for parking and curb extensions were built at some pedestrian crossings. All of these examples were at one time four-lane roads without these amenities and with higher speed traffic.

In **Fig. 3**, an example is shown of a road without a road diet, a typical four-lane arterial in a suburban area. The figure on the right is modified to show what the road would look like after a conversion to two-lanes and a TWLTL with bicycle lanes along the side.

Figure 3 Livingston Ave, New Brunswick, NJ. Current configuration and simulated photo showing potential road diet. *Source: Author.*

Other Road Diet Configurations

While the classic and most common road diet involves reducing a four-lane road to three-lanes, other configurations are possible. These can also involve reductions in lane-width and changes in shoulder widths. For example, a four-lane road could be reconfigured with a TWLTL and maintain four-lanes of moving traffic. This is done by reducing lane and shoulder widths. While perhaps not having the safety benefits of a reduction to three-lanes, there can be operational benefits of having the turning lane. Other examples could be reducing the lane width of a current three-lane configuration to provide room for a larger shoulder or bicycle lanes.

Another design option is to introduce a hard median and converting from four-lanes to two-lanes. Since a hard median restricts turning movements, roundabouts (traffic circles) can facilitate U-turns (and also create safer road junctions). An example of this is a conversion along La Jolla Boulevard in San Diego, CA. In this case a large arterial with five lanes (including left-hand turn lanes) was reduced to two-lanes with five roundabouts along a commercial corridor (**Fig. 4**). This street handles about 22,000 vehicles per day. An additional benefit of this design was a large reduction in pedestrian crossing times, which actually reduced vehicle waiting times at crosswalks ([Logan, 2017](#)).

Road diets is largely a North American term, representing efforts to ameliorate past over-building of roads. In Europe there have been substantial efforts to reallocate road space to pedestrians and cyclists. These have ranged from pedestrian-only zones in many European cities, to extensive bicycle networks (usually separated from vehicle traffic). Traffic calming largely originated in Europe and some road diets follow similar principles of using design to reduce vehicle speeds and improve safety for all users.

Figure 4 La Jolla Blvd., Bird Rock, San Diego, CA. *Source: Google Maps.*

Complete Streets

Road diet implementations are also a method for developing *Complete Streets*. These are broadly defined as streets designed to serve not just motorized vehicles, but all modes—pedestrians, cyclists, and transit users (New Jersey Dept. of Transportation, 2017). In addition, a complete street should allow safe use by children, disabled users, and older population groups. A road diet implementation that also serves the needs of these users would be consistent with the philosophy of reallocating street space so that all users can safely access the transportation system. To make a complete street safe enough for all users, motor vehicle speeds need to be reduced especially at pedestrian crossings.

In North America, there have been a proliferation of complete street policies implemented at the state, regional, and local level (Gregg and Hess, 2019). Traditionally when new roads are constructed or existing roads undergo a major renovation, design guidelines focus on only serving motor vehicle needs. Any attempt to, for example, add a bicycle lane or create safer pedestrian crossing points is seen as an imposition on the flow of vehicles, and requires special exemptions. Complete Streets policies switch this logic around. Most of those policies implemented require road and highway agencies to justify not providing access for all users; the default policy under Complete Streets is that now the street will serve all users in a safe and equitable manner. As these policies have spread it allows local areas to implement road diets as part of their Complete Streets policy.

Benefits of Road Diets

In assessing whether to convert an existing four-lane road, the primary motivation is normally to achieve safety benefits. Other benefits can also occur, including improved vehicle flow, community development and livability, and even reductions in vehicle emissions.

Safety Benefits

The safety benefits attributable to road diets derive from both speed reductions and fewer potential conflict points for vehicles. Speed reductions can occur because lead vehicles control the speed of following vehicles. Weaving and passing movements, while still possible, are much less likely to occur as vehicles stay in a single line. Those vehicles making left turns or turning left into the road have a designated turning lane, so as to not block through traffic and reduce rear-end and side-swipe collisions (Thomas, 2013).

Average speeds are typically lower by up to 5 mph (8 km/h) after implementation. Excess speeding is also reduced. Speed differentials between lanes and traffic moving in the other direction are reduced; the median provides an enlarged buffer between opposing traffic streams also improving safety.

Pedestrian safety is improved, both from reductions in speed, but more importantly from reduced crossing distances. If curb extensions are part of the road diet, this allows pedestrians to more safely cross the street. A bicycle lane or wider shoulder, with or without parking, can provide added buffer space between vehicles and pedestrians on the sidewalk. If a bicycle lane or wide shoulder is part of the road diet, then this provides an additional safety benefit for bicyclists and may increase the likelihood of cyclists using the road. In much of the United States, a stripe separating a bicycle lane from an automobile travel lane is deemed to give acceptable safety. In much of Europe, striping is not considered enough, but a curb or pollards with reflectors are installed as well. Some cities, such as New York City, are placing bicycle lanes between the curb and a line of parked cars (though these are not necessarily associated with road diets).

While safety benefits of road diets are generally recognized, very few studies examined impacts before and after conversions. A review of studies concluded that crash reductions of between 19% and 47% are expected, depending on road type and the location of the road (Thomas, 2013). The reduction of 19% was associated with roads in large urban areas, while 47% reductions were associated with rural roads in small urban areas. It is more than likely that these estimates are inaccurate for any specific case, given the dearth of studies. Thus, while road diet conversions will likely reduce crashes, there is great uncertainty on the magnitude of the reduction. This may make it difficult for decision makers to promote road diet conversions.

It is clear that pedestrians will benefit greatly from road diets when speeds are reduced. A study of a large number of crashes in the United States found that the risk of severe injury increases with speed (Tefft, 2011). For example, a reduction of 5 mph (8 km/h) would reduce severe pedestrian injuries by about 16%.

Operational Effects

One of the main concerns expressed by those opposed to road diet conversions is that any reduction in capacity will lead to congestion. While road diets effectively take a lane of traffic away, there is actually minimal operational impact. If there are a substantial number of left-turn (cross-traffic) movements along a four-lane road it effectively is already operating with only one lane in each direction as turning vehicles block one of the through lanes. Most road diets do not affect operations up to usage of between 20,000 and 25,000 vehicles per day (Stamatiadis et al., 2011; Knapp et al., 2014). At levels greater than this, left-turning movements would likely be forbidden so that all four lanes can be effectively used. Many studies have found no increase in vehicle delay, or even reductions in vehicle delay, with road diet conversions at levels below 25,000 vehicles per day.

Figure 5 “Fire lane” marked along median, Canal Pointe Blvd., West Windsor, NJ. Conversion completed in 2017. *Source: Author.*

One issue is that if there are frequent traffic signals, a road diet may result in excess queuing at signals backing up into the area of adjacent signals. This can be mitigated by coordinating traffic signals at the posted speed limit. It typically is not an issue when peak-hour traffic volumes are below about 1750 vehicles per hour (or 875 in each direction). Traffic signals can also be replaced with single-lane roundabouts, as illustrated in [Fig. 4](#).

Emergency response vehicles also see a benefit from road diets using two-way turn lanes ([FHWA, 2017](#)). While often police and fire services oppose road diets, in reality the median lane provides an unobstructed travel lane when needed by emergency responders. Some road diet implementations actually mark the median lane as a “fire lane” ([Fig. 5](#)). The conversion shown in [Fig. 5](#) was previously a four-lane road and did not have a shoulder.

Livability Benefits

Road diets are seen as a way to improve the livability and quality of life for those living on or near the converted street ([Knapp et al., 2014](#)). This can happen when speeds are reduced and increased buffers are provided between the sidewalk and the traffic stream. Both can create a more pleasant and safer walking environment leading to more people walking along the street. Vehicle noise is also reduced as speeds are lower. Air quality improvements have been found to occur, though this may matter less as vehicles electrify ([Shu et al., 2014](#)). A smoother traffic flow reduces stop and go driving that may lead to hard accelerations and decelerations, which are associated with higher emissions, in particular particulates from brake pads and tires. In commercial districts, lower speeds, easier street crossings and a more pleasant environment can also spur increased economic activity. All these benefits can improve public health especially in traditionally underserved communities.

Ease of Implementation

Most road projects undergo large studies and detailed engineering assessments before a decision is made to build the project. These assessments are time-consuming and expensive. Road diets, on the other hand, can be implemented quickly and cheaply, assuming there is political will to improve safety. In most cases, all that is needed is the removal of existing pavement markings and replacement with new traffic stripes to delineate the lanes. If a resurfacing of the road is scheduled, the new stripes will add minimal costs to the project and maybe none at all ([FHWA, 2016](#)). If for some reason the restriping creates unexpected problems, the road diet can be quickly and cheaply reversed. This falls within what are considered tactical urbanism approaches to improve quality of urban and suburban areas. Testing of changes to street design, via restriping, can demonstrate the effectiveness of the changes without major investment.

Costs

The Federal Highway Administration provides a rough estimate of how much a four-lane to three-lane road diet conversion will cost ([FHWA, 2016](#)). Assuming that a bicycle lane is included, the total costs of removing and restriping comes to about \$100,000 per 5000 ft (~1500 m) of road. If the road surface is repaved, the addition of bicycle lanes adds between \$18,000 (simple striping) to \$46,000 (with signage and bike lane road markings) more to project costs. These estimates are based on 2015 USD estimates. Since roads are periodically restriped and repaved, additional costs will be minor as they would be part of the planned project.

The reallocation of road space achieved with a road diet is cheaper than alternative approaches that might require expanding the width of the right-of-way. For example, if sidewalks and bicycle lanes are added to an existing road without using the existing right-of-way, then additional costs for land acquisition and storm water drainage may be incurred. In many cases, this may not be feasible if space is constrained in an urban or suburban area. Adding turning lanes to a four-lane road may also require widening the right-of-way at selected intersections, adding substantially to project costs.

Political Context and Impediments

Even though road diets provide many benefits, there is often political and public opposition to converting existing four-lane roads, even when there are demonstrated safety issues. Much of this opposition is likely due to concerns that traffic congestion will increase since two travel lanes are being eliminated. As discussed earlier, operational effects are usually minor, unless the road exceeds peak-hour vehicle travel of about 1750 vehicles. Some may also complain that speeding is made more difficult as they do not believe it poses a risk; they also oppose having the freedom to pass and weave around slower moving vehicles. Political leaders and traffic engineers are also loath to experiment with untested approaches in their communities.

One solution to opposition is to propose a pilot restriping or “demonstration project.” As noted above, this is a cheap intervention that is easily reversible. If the community sees the benefits and that there is no change in congestion levels, then implementation is more likely to succeed.

Existing requirements and guidelines may also be an impediment to a fast implementation, not least in the United States. Many states may require that any change to a road layout must undergo a detailed engineering analysis, in particular to determine impacts on traffic Level of Service (LOS). This type of analysis usually requires contracting work out to an engineering firm with expertise in applying Highway Capacity Manual procedures and simulation models to evaluate changes in LOS at each intersection along the proposed road diet (TRB, 2010). Often, these studies can cost more than the actual restriping that is called for! Additional delay in project implementation also means that the safety benefits of the road diet are deferred. The United States is not alone as in many other countries mobility trumps safety.

Sweden’s Vision Zero program is an exception to this and has dramatically changed public perceptions of mobility versus safety in the Swedish road transport system. As noted in this Encyclopedia’s entry on Vision Zero, “Mobility becomes a function of safety rather than the other way around” (Belin, in press). A comparison can be made with the aviation network, “if we discover safety problems in our aviation system that might threaten people’s lives we stop the air traffic until we have fixed the problem. Luckily, we do not have to stop the road traffic in order to achieve safe mobility, since it, in most cases, is enough to reduce speeds” (Belin, in press).

Another source of delay is over-design of the road diet. For example, pedestrian curb extensions can be added and provide additional safety benefits. These obviously add costs, including additional delay in designing the infrastructure changes, and may require further changes to accommodate storm-water drainage. New signaling systems may also be required and might help with any signal retimings needed to avoid operational problems. While these might be beneficial improvements, they should not delay the restriping. The key message is that road diets are quick and cheap to implement.

Criteria for Road Diets and Assessment Procedures

In the United States, many state, county, and city agencies have developed various criteria for considering road diets. These typically include traffic volume (not exceeding 25,000 vehicles per day), speed of vehicles on the road, and number of vehicle crashes and particularly those involving pedestrians (Knapp et al., 2014). In most cases, the road is identified as having a safety problem from excess crashes and potential conflicts with pedestrians, either from inadequate space for pedestrians or speeding traffic (in excess of posted speed limits). While these criteria suggest the need for an intervention, other criteria can impact the effectiveness of a road diet. These include the number of driveways and cross-streets, signal spacing, freight traffic volumes, and bus routes along the street. A route with a large number of driveways and cross-streets with left-turn movements would likely see improved traffic flow from a road diet implementation. Buses without a turnout lane, may delay other traffic when only one travel lane is available. Signals can be retimed to mitigate any traffic problems.

One simple way to assess the benefits of a road diet is to evaluate the costs and benefits. The primary benefit is a reduction in crashes and in particular injuries and fatalities. As noted previously, conversion costs mainly consist of restriping and are trivial. If travel times and level of service in the corridor increase, then there is a cost associated with increased travel delay. Both crash costs and travel delay can be monetized to produce a cost-benefit analysis, discounted over a 20-year time period. The USDOT provides guidance on benefit-cost analysis including valuations of statistical life and valuations of travel time (Office of the Secretary, USDOT, 2018).

There are very few studies of the safety benefits of road diets, with the rule of thumb being between 19% and 47% reductions in crashes (Thomas, 2013). However, in reality, it is not possible to predict the actual crash reduction from any specific intervention. The relevant consideration is what level of crash reduction is needed to justify the costs of a road diet conversion? While many road diets will have little to no impact on corridor travel times, due to the road being a de-facto three-lane road, decision makers may still believe there will be congestion impacts. Thus, one approach is to assume large travel time increases and determine what crash

Figure 6 Graphical analysis of trade-off scenarios between travel time costs and crash reduction, showing break-even NPV values. This analysis shows that benefits exceed costs when crash reduction is between about 22% and 50%. Source: [Noland, 2018](#)

reduction is needed to have at least a zero net benefit (or benefit-cost ratio equal to 1). In some cases, the objective of the project may be to reduce speeds and speed variance, and thus, this would increase travel times. A sample graphic showing a benefit-cost trade off analysis is shown in [Fig. 6](#). This analysis only examines safety benefits and excludes many of the other benefits of a road diet, including better pedestrian access, bicycle lanes, health and livability of the area near the road diet; it also assumes a large increase in travel times from a reduction in speeds of 5 mph (8 km/h) based on liberal assumptions on average traffic flow ([Noland, 2018](#)). In this example, depending on the assumptions of the analysis, a crash reduction of anywhere from about 22% to 50% results in benefits equal to costs.

Summary

To summarize, road diets are an effective and cheap safety countermeasure that involves reducing the number of motor-vehicle travel lanes. They can be implemented quickly if agencies forego much of the detailed traffic flow analysis often required for changes in road design. There may be signalization changes needed, but these can be adjusted after the road diet is implemented. Road diets are easily reversible if not deemed successful at reducing crashes or if they introduce other problems. Any resurfacing project is an opportunity to implement a road diet. The benefits of road diets also go beyond just expected crash reductions. These include livability benefits that result in more walkable and pleasant conditions along the road, noise reductions, emissions reductions, and potential increases in commercial activity.

Background

Every year, transportation professionals face the increasing demand for safer roads. Various strategies have been applied to reduce traffic conflicts, injuries, and fatalities. One of those strategies, hot-spot management, has been applied extensively. A hot spot is a colloquial term for roadway segments or intersections that show a significantly higher rate or frequency of fatalities and injuries or overall crashes than others in a cohort. Even though a hot spot can be identified through a clear and treatable crash pattern, the specific countermeasures may act only as a "band-aid" solution and not address the broader safety issue. Transportation professionals should migrate from reactive hot-spot management to a more proactive approach that fixes safety deficiencies before crashes happen. One effective proactive approach is the safety audit. A road safety audit (RSA) is a formal safety examination of a future road or traffic project or an existing road by an independent, qualified, and multidisciplinary team who reports on the project's crash potential and makes recommendations for safety treatments. It is worth noting that the concept of safety audit has been applied to other transportation modes such as aviation safety audits, marine (or maritime) safety audits, and railway safety audits. However, the primary purpose of RSA in other modes is to assess the degree of compliance with safety regulatory requirements and standards.

RSAs can be conducted in any phase of a road project's life cycle, which includes planning, preliminary design, detailed design, work zone traffic control plan, project construction, preopening, and postconstruction. Although an audit's scope, purpose, focus, and complexity will vary depending on the phase, the essential elements of an RSA do not change. RSAs need to be performed by a team that is (1) independent of the project to ensure an impartial assessment, (2) multidisciplinary to ensure the audit is complete and comprehensive, and (3) capable of giving formal and constructive recommendations. This paper covers the fundamentals of RSAs, including definitions and terminologies, steps and procedures taken to perform RSAs, and the costs and benefits of conducting an RSA. Readers will also learn about the tools used during a safety audit and be introduced to case studies involving typical highway projects, pedestrian and bicyclist facilities, work zone management, and road weather safety. The content could be used as a reference guide for those interested in the concept of an RSA and as an introductory source to support further exploration.

The History and Evolution of Road Safety Audits

The concept of an RSA originated in the United Kingdom in the 1980s when some newly completed roads were experiencing a high number of crashes and injury severities that could have been prevented. By 1991, it became a national mandate in the United Kingdom for all national trunk road and freeway projects to undergo an RSA as long as resources allow. The safety audit philosophy was introduced in Australia and rapidly expanded to other countries such as Canada, Denmark, the Netherlands, Germany, Switzerland, Sweden, Norway, and South Africa. Developing countries such as Malaysia, Singapore, Bangladesh, India, Mozambique, and the United Arab Emirates have also introduced RSAs.

The first RSAs in the United States were implemented at the design stages of projects in Pennsylvania around 1997 after the Federal Highway Administration (FHWA) visited Australia and New Zealand to review their processes. The FHWA conducted 14

pilot projects in different states around the nation. Other states and local agencies followed suit and developed their own procedures and methods to carry out safety audits in pavement overlay programs, pavement rehabilitation, restoration, and resurfacing (3R) projects, and even for megaprojects (e.g., the Marquette Interchange reconstruction project in Milwaukee, Wisconsin, United States). The boom of RSA practices led to the publication of the National Cooperative Highway Research Program (NCHRP) Synthesis 321: *Roadway Safety Tools for Local Agencies: A Synthesis of Highway Practice* in 2003 (Wilson, 2003), and later Synthesis 336: *Road Safety Audits: A Synthesis of Highway Practice* in 2004 (Wilson and Lipinski, 2004) (<http://trb.org/bookstore/>). In 2006, FHWA established the *FHWA Road Safety Audit Guidelines* to promote RSAs and their integration into existing safety management systems and engineering practices (Ward, 2006). Relevant training materials and courses have been developed by the FHWA National Highway Institute (NHI) and are available through <http://safety.fhwa.dot.gov/rsa>.

The 2012 report *Road Safety Audits: An Evaluation of RSA Programs and Projects* demonstrates the effectiveness of RSAs by outlining nine RSA programs and five RSA projects in the United States funded by FHWA, as well as numerous case studies from state and local agencies and nonprofit organizations such as the Institute of Transportation Engineers and the American Automobile Association (Nabors et al., 2012). Australia's 2009 edition of the *Guide to Road Safety Part 6: Road Safety Audit* is currently being updated to include Safe System principles and account for the rapid development of predictive safety models (Austroads, 2019a; Austroads, 2019b).

Benefits and Costs of Road Safety Audits

RSAs are beneficial because it is better to be proactive and prevent crashes and fatalities rather than react to them. The long-term benefits of RSAs are substantial. From the road owners' perspective, RSAs save the potential throwaway and construction costs by correcting safety deficiencies before roads are in service. Safe roadway designs and operations also mean less potential for lawsuits. More importantly, adopting RSAs shows an agency's strong commitment to safety. Raising safety awareness at all levels is invaluable, as it leads to better decision-making that considers multimodality and human factors.

Sometimes the benefit of an RSA can be quantified by converting reduced crash frequency or severities to a monetarized value if the cost effectiveness of a safety countermeasure is known. The process of performing a benefit-cost analysis is detailed in *Chapter 7 Economic Appraisal* of the *Highway Safety Manual* (AASHTO, 2010). According to the FHWA, one of the most cited studies of the benefits of RSAs was conducted in Surrey County, United Kingdom. The study found that the average annual fatal and injury crash frequency at the audited sites decreased by 1.25 crashes per year versus only 0.26 crashes per year at unaudited sites; this suggests that RSAs are 5 times more effective in reducing fatal and injury crashes. The FHWA Road Safety Audit website (<https://safety.fhwa.dot.gov/rsa/resources/>) has published the economic analysis results for several other studies.

The cost of an RSA includes RSA team costs, design team and project owner costs, and implementation costs. The cost of RSAs varies greatly by audit project size, scope, and complexity. Typically, conducting RSAs and implementing the recommended safety countermeasures in design are estimated to be 5% of the overall engineering design fees. However, the cost ultimately depends on agencies' flexibility and creativity in integrating RSAs within existing programs and projects.

Steps to Perform Road Safety Audits

Compelling case studies and evidences have shown that timely RSAs provide cost-effective solutions to improving road safety. An RSA usually follows the eight-step audit process which has become the industry standard (Ward, 2006):

- Step 1: Identify the project to be audited. In this step, the public agency is responsible for identifying the project or existing road to be audited.
- Step 2: Select the RSA team. In this step, the public agency is responsible for selecting an independent, qualified, and multidisciplinary team of experts suitable for the project.
- Step 3: Conduct a preaudit meeting to review project information. In this step, a meeting is called between the project owner, the design team, and the audit team to discuss the context and scope of the RSA and review all available project information.
- Step 4: Perform field reviews under various conditions. In this step, the RSA team reviews information obtained from Step 3 to gain insight into the project and safety concerns and prepare for the field visit. The field visit helps the team gain further insight into the project and further verify/identify areas of safety concern.
- Step 5: Conduct an audit analysis and prepare the findings. In this step, the RSA team identifies, analyzes, and prioritizes safety concerns and locations and summarizes the findings that include recommendations for the formal RSA report.
- Step 6: Present audit findings to the project owner/design team. In this step, the RSA team orally reports the key findings to the project owner and design team.
- Step 7: Prepare the formal response. In this step, the project owner and/or design team provides a formal response to the RSA team with regard to each safety issue listed in the report and explains why some of the RSA suggestions could not be implemented.
- Step 8: Incorporate findings into the project when appropriate. This final step ensures that the corrective measures outlined in the response report are completed as described and in the time frame documented.

Road Safety Audits in a Road Project's Life Cycle

Although RSAs can be applied at every stage during the life cycle of a road project, applying audits earlier on in the planning stage and preliminary design phase offers the greatest opportunities to rectify any safety deficiencies and avoid throwaway costs. The cost for correcting or retrofitting will be higher as the project advances into later stages; however, RSAs that occur later in the process can also be beneficial as unique and new safety problems may emerge (Ward, 2006).

Three types of RSAs may be conducted during the preconstruction phase: planning or feasibility, preliminary design, and detailed design. An RSA during the planning stage focuses on items such as: vehicles to be accommodated with the proposed project, design speed, access to surrounding developments and connection with other routes and the number of spacing of intersections.

The preliminary stage audit can be performed when 30%–40% of the design is finished, and includes topics such as drainage, landscaping, accesses to developments, accommodation for maintenance and emergency vehicles, and parking provisions. It also includes design issues such as cross-section elements, alignment, sight distances, and intersection layout. The preliminary audit also considers safety issues specific to special road users (pedestrians, bicyclists, and public transport). Lighting, signage, and pavement markings are also considered during this audit.

Lastly, the detailed design audit can be conducted as soon as approximately 60%–80% of the design is finalized. The detailed design audit is critical as it is the last opportunity to review the design before construction begins. Depending on the type of roadway, the detailed design covers design features related to drainage, pavement skid resistance, geometry, medians, shoulders, barriers and guardrails, readability, traffic signals, signs, markings, special road users, and parking provisions.

Construction phase RSAs can be conducted during the construction preparation period, during the actual construction period, and during the preopening time period. The RSA team can conduct three types of RSAs using project as-let or as-build plans: work zone traffic control plan RSAs, changes in design during construction RSAs, and preopening RSAs. When performing a work zone traffic control plan RSA, the audit team should ensure that safety is adequately considered in the maintenance of traffic plan and the work zone traffic control plan. Safety items to consider for this RSA include the design of temporary roadways and transition areas, appropriateness of temporal traffic control devices, information consistency between temporary and permanent traffic controls, and possible impacts for all road users, including pedestrians, bicyclists, and the disabled. The RSA taking place at the changes in design during construction stage requires the team to envision situations where construction may lead to unforeseeable safety problems that may not be obvious. Lastly, the preopening RSA is the last chance for the team to consider any safety aspects of the design before the project is opened to the public. The team should perform a thorough field review to identify any necessary modifications related to illumination, traffic signs, pavement markings and delineation, and fixed object hazards.

Postconstruction phase RSAs take place on existing roads. The RSA team should observe all interactions between road users and roadway facilities during the day and night, note the conflicts and report any safety concerns. Crash data may become available during postconstruction RSAs, but it should not be the sole reason for the RSA. Crash data can be used to validate safety concerns identified through the RSA and to preclude potential safety issues.

Road Safety Audit Tools

The most commonly used RSA tool is the checklist, or, more appropriately, the prompt list. The word “prompt” underscores that the role of the list is to assist (not replace) knowledge and experience. Prompt lists pose questions intended to guide auditors to think “what can be done differently as a result of an RSA?” The purpose of an RSA prompt list is to help auditors identify any potential safety issues rather than check only common design standards.

General prompt lists can be organized by RSA stage in the project life cycle. Custom prompt lists have been developed for different subjects such as pedestrians and bicyclists, transit users, work zones, or specific crash types (i.e., wrong-way driving). Prompt lists can be used when reviewing project data, conducting site visits, conducting analyses, and writing RSA reports.

Prompt lists are migrating from paper forms to computerized applications. The Road Safety Audit Toolkit, developed from the Austroads checklists, is an online computer program that facilitates the audit process. The software assists auditors by prompting them with questions so that they can efficiently organize their findings in a structured manner. The toolkit automatically generates RSA reports. The software is free for download at www.rsatoolkit.com.au. The Austroads Road Safety Engineering Toolkit, which provides solutions to safety concerns, can be used in conjunction with the Road Safety Audit Toolkit. Treatments can be selected by crash patterns, or by specific category of road safety deficiencies such as signalized intersections. The engineering toolkit can be accessed at www.engtoolkit.com.au.

It is worth emphasizing that RSAs are not auditing design standards, so the checklists cannot substitute a design manual; but they can be used by roadway designers to help proactively identify safety issues during the design process. The Interactive Highway Safety Design Model (IHSDM) has been incorporated into the audit process for several studies in order to evaluate the safety and operations of a highway project. As a primary design tool, IHSDM can be useful in providing a quantitative assessment of the safety implications of various design alternatives. IHSDM is available for free download at www.ihsdm.org.

Case Studies

Although it is impossible to list every type of case study, the following cases represent three very different applications: pedestrian and bicyclist safety, work zone management, and road weather safety.

Transit Access Safety Audit

The purpose of the study was to conduct an RSA for the existing transit access roads at Sun Trans and the City of Tucson, Arizona, United States. The study site is located in an urban area with a high level of multimodal interactions among passenger vehicles, pedestrians, bicyclists, and transit vehicles. The RSA team included members from the City of Tucson, Pima Association of Governments, Sun Tran, the Tucson Police Department, and RSA consultants. Given the large size of the study site, the RSA team identified five focus areas at the intersection and segment levels. After completing the field visit and data analysis, which included crash data from the study area for the last 6 years, the team identified several safety concerns. Some concerns were unique to transit stations and stops, such as the trespassing of private vehicles into the transit center, street closures, and parking. Other concerns were related to pedestrian safety in general, such as reduced sight distance, large turning radius, long crossing distances, and compliance to traffic signals. The team recommended installing larger and more conspicuous "Do Not Enter, Authorized Vehicles Only" signs to reduce the number of trespassing vehicles, adjusting certain parking zones to eliminate violations that interfere with transit vehicles, improving pedestrian crossings through extended curbs and adding a leading pedestrian signal phasing, and applying effective pavement marking to reduce user confusion and improve operations of transit vehicles (Goughnour et al., 2016).

Specific guidelines and prompt lists for pedestrian road safety are available in the *Pedestrian Road Safety Audit Guidelines and Prompt Lists* (Nabors et al., 2007). The guide offers a better understanding of the needs of pedestrians of all abilities, and consists of a Knowledge Base and Field Manual. The Knowledge Base section discusses how to use the guide and includes the basic principles of pedestrian safety (i.e., pedestrian characteristics, pedestrian crashes, and other pedestrian considerations to include in the RSA process). The Field Manual section includes the guidelines and prompt lists.

Active Work Zone Safety Audit

The purpose of the study was to perform a work zone road safety audit (WZRSA) for an active work zone phase. The selected construction project was an urban freeway with the posted speed limit of 65 mph. The multidisciplinary RSA team included safety engineers and work zone engineers from the FHWA, contractors, RSA consultants, as well as designers, traffic and safety engineers, and construction engineers from the Florida Department of Transportation. The RSA team performed a review of two interchanges within the work zone and its adjacent areas. Upon reviewing the project information, plans, and crash data, the team visited the transportation management center to watch traffic patterns and driver behavior from surveillance cameras. Next, they visited the field to closely observe how drivers interacted with the temporal traffic control and configuration of the work zone. The team observed speeding in work zones at night when congestion had decreased, as well as vehicular conflicts at merge/yield areas. In the RSA report, the team recommended increased enforcement during off-peak hours, improving pavement markings and yield signs, and extending the merge area by shifting the barriers (Atkinson, 2013).

The case study exemplifies the application of the *WZRSA Guidelines and Prompt Lists*. The guide includes an eight-step process for performing formal work zone safety examination to improve the safety of construction workers and road users. In particular, a WZRSA assesses the temporary nature of the design that will be removed once the work zone is completed. Agencies can incorporate elements of WZRSA into their current practices by considering work zone safety and mobility at each stage of a project's life cycle (i.e., planning, preliminary design, final design, and active work zone). Mobility considerations that affect safety (i.e., queuing and congestion) can also be considered. The guide points out that impacts on safety and mobility should not be limited to the actual work zone limits. It also notes the importance of considering possible impacts to the construction project's time line, and advises transportation agencies to consider any scheduling issues before beginning the WZRSA.

Road Weather Safety Audit

Most RSAs are performed under favorable weather conditions; consequently, the impact of traffic operations and safety during adverse weather conditions (i.e., snow, rain, sleet, and fog) often are not considered. A study funded by the Wisconsin Department of Transportation explored the possibility of institutionalizing the road weather safety audit (RWSA), and in doing so the study heightened awareness of weather issues that impact infrastructure and operations. The study developed a comprehensive and formalized RWSA for Wisconsin, defined processes and procedures for RWSAs under department organizational structure, designed prompt lists, and identified and provided key data sources for different stages of the audit process (Qin et al., 2013).

Prompt lists were developed for five stages: feasibility, preliminary design (30% of the design stage), detailed design (60% of the design stage), preopening, and existing road facilities. A Weather Constraints section was included in each stage to help evaluate and improve weather-related road safety issues.

Conclusion

An RSA offers a proactive and practical approach to assessing the safety of a road any time during its life cycle. Safety deficiencies are identified by an independent, qualified, and multidisciplinary team, and corrective actions can be taken in the early stages of a project (i.e., before a road is open to the public). Through the lens of RSAs, the safety performance of a road will be evaluated comprehensively, impartially, and preemptively. Evaluating a roadway's safety, with or without crash data, yields great opportunities to address a wide range of safety problems. Over the last 4 decades, RSAs have evolved from isolated pilot projects to programmatic and systematic practices endorsed and adopted by many countries, including the United States.

RSAs are successful only when they follow a structured and formal process. RSA tools, from paper-based prompt lists to today's computer-aided software, have played a significant role in promoting and facilitating the application of RSAs. As the process has become more formalized and the general prompt lists have become more standard, custom RSAs for specific topics (i.e., pedestrian and bicyclist safety, work zone safety, and road weather safety) have been developed in response to emerging safety needs. Although safety subjects will become more diverse as new safety needs continue to grow, the essential elements of RSAs will remain intact: a formal examination by an independent team to identify existing and potential safety concerns for all road users.

An RSA is a crucial safety tool for transportation professionals. The regular use of RSAs promotes and even mandates the consideration of safety during project planning and development, design, construction, operations, and maintenance. RSAs involve all safety stakeholders, from decision-makers to practitioners. RSAs are in accordance with the safe systems approach to road safety management that uses shared responsibility and knowledge to ensure that human error does not lead to death or life-changing injuries.

Biography

Dr. Xiao Qin is a Full Professor in the Department of Civil and Environmental Engineering at the University of Wisconsin-Milwaukee, United States. He has nearly 2 decades of experience in the areas of highway safety, traffic operations, and GIS applications in transportation. He has authored more than 150 technical papers, and won several best paper awards presented by the Transportation Research Board (TRB) and the Institute of Transportation Engineers (ITE). His research has been instrumental in identifying critical safety issues in transportation systems and addressing them with effective methodologies. He is a member of several highway safety TRB committees. He is an associate editor of the *Journal of Transportation Safety & Security* and serves on the editorial board of *Accident Analysis and Prevention*. He received his PhD in Civil and Environmental Engineering from the University of Connecticut.

History

Roadside Safety Barriers (RSBs) have evolved as transportation modes have evolved. When horse drawn buggies and bicycles were common, traveling speeds, vehicle size, and the opportunities for injury were limited. When motorized vehicles were developed in the mid-1800s, things changed. Mass production of the Ford Model T in 1908 created affordable, higher speed transportation. This meant more people were able to drive at higher speeds and the likelihood of injury escalated. One of the first recorded automotive-related deaths occurred in 1869 when a steam-powered carriage struck a bump and one of the occupants was ejected and run over by the same vehicle (Smallwood, 2013). One of the first recorded impacts with a roadside hazard was recorded in Ohio City, Ohio, in 1891 when James William Lambert driving one of the first single cylinder gasoline automobiles struck a tree root, lost control, and subsequently smashed into a hitching post.

Early guardrail designs used wire ropes, wire mesh, or timber planking as the longitudinal beams or redirective components, and they were mostly supported on timber posts. As traffic speeds increased, 3.6 mm (10-gauge) sheet steel replaced timber beams to accommodate the higher impact energies. The states of Georgia and Missouri Transportation Departments were some of the first jurisdictions to do full-scale testing on guardrail systems in the early to mid-1930s (Division of Design Bureau of Public Roads, 1936). At this time, well over half of the world's private automobiles were located in the United States and most research on and development of roadside barriers were conducted in the United States, and that was the case for decades thereafter as well. This motivates why this article focuses on work and design in the United States.

Some of the early traffic barriers were placed on bridges. Through truss bridges most likely had railings to protect structure rather than providing safety to occupants of errant vehicles. Some open girder-type bridges did have railings, as the consequence of leaving bridge was a known danger. However, initial designs were merely more delineation than an actual longitudinal barrier.

By 1936, approaches to bridges were begin to have guardrail designs incorporated as shown in Fig. 1 from the US Department of Agriculture, Division of Design Bureau of Public Roads (Division of Design Bureau of Public Roads, 1936).

Traffic deaths escalated as traffic volumes and speeds increased. By 1930, total motor vehicle-related deaths in the United States alone had increased to approximately 30,000, more than double the number in 1920. Clearly, motor vehicle deaths were becoming something that needed to be addressed. Fig. 2 shows US motor vehicle deaths since they were first recorded in the 1920s to the current day (Bratland, 2019).

The forgiving roadside concept gained popularity in the mid-1960s and was published in the American Association of State Highway and Transportation Officials' *Highway Design and Operational Practices Related to Highway Safety*, otherwise known as the Yellow Book (American Association of State Highway Transportation Officials, 1967). The Yellow Book gained wide acceptance in the highway safety community and put forth the four steps of the forgiving roadside concept where hazards were (1) eliminated, (2) relocated, (3) made into breakaway devices, or (4) shielded. The last option is accomplished with RSBs.

Roadside Safety Barriers

RSBs such as wire rope or cable barriers, w-beam guardrail, and concrete barriers are placed parallel to the roadway to redirect errant vehicles and prevent impacts with roadside or median hazards. RSBs are used when the roadside hazard presents a greater hazard than the roadside barrier itself. RSBs are a hazard themselves. The first choice in roadway design is to remove all hazards adjacent to the roadway and grade the roadside providing a possible recovery area for drivers leaving the roadway. The obvious next question is, how far away to remove hazards from the roadway? Prior to the highway speeds being increased, the design was to provide a clear zone of recovery for at least 30 ft. (9 m) from the edge of travel lane. With today's speed limits, in the United States reaching 85 mph

Figure 1 Design of bridge approach guardrails.

(137 km/h), clear zones of recovery can exceed 70 ft. (21 m), specifically in median applications where crossover accidents are almost always severe. These requirements often make designers consider the placement of some type of RSB.

RSBs vary in stiffness. They are considered flexible (wire rope), semirigid (w-beam), and rigid (concrete barriers). Selection of barrier type depends on site conditions, travel speeds, traffic mix, and traffic volumes. Site conditions include hazard type and location, drainage needs, topography, right-of-way extent, etc. Travel speeds and traffic mix dictate the performance level needed from the RSB and traffic volumes may influence designers and maintenance crews toward more rigid systems that require less maintenance. The most flexible systems are generally lower in total cost to install but do have maintenance costs once impacted. Rigid systems have lower maintenance costs but are more costly on the original install. As the name implies, rigid systems have low deflections but impart higher accelerations to occupants of errant vehicles. If medians have been consumed by adding lanes for increased capacity, eventually there will be an insufficient space for expected deflections of flexible or semirigid systems and rigid systems are required. Additionally, there is little space left for maintenance crews to safely service damaged RSBs. Therefore, rigid systems become the barrier of choice in these locations.

Wire rope systems are used in both roadside and median applications. These systems are considered the most flexible with deflections reaching 3.7–4.6 m (12–15 ft.) when impacted by heavier vehicles at high impact angles and speeds. This results in the lowest rates of injuries to occupants. Greater deflection equates to lower lateral deceleration values, in turn, causing fewer injuries. The roadside or median must be able to accommodate these greater deflections without a high risk of secondary impacts to objects in the deflection area. One exception to this concern was investigated in Sweden with the use of two + one roads where high-tension wire ropes replaced double yellow lines on undivided roadways with two lanes in one direction and one lane in the opposite direction. The median strip is typically 1.75 m (5.74 ft.), so only about 0.8 m (less than 3 ft.) from barrier to the oncoming lane which is 3.75 m (12.3 ft.) or 2×3.25 m (2×12.3 ft.) in the double lane direction. So, in theory there should be many accidents where oncoming vehicles are hit but in reality very few occurred. Head-on collisions are “eliminated” and overall fatalities reduced by over 75%. Obviously the number of reported crashes goes up with numerous accidents involving single-vehicle crashes into the wire ropes.

Figure 2 US motor vehicle deaths and trends. Source: Dennis Brantland, Wikimedia with permission.

Early wire rope systems were untensioned and were $\frac{1}{2}$ in. or less in diameter and were initially supported on wood posts. Subsequent designs were suspended on concrete and steel posts. By the 1930s the diameter of wire ropes increased to $\frac{3}{4}$ in. and the structure of the wire rope included three wire strands with seven wires in each strand. This is the same wire rope construction used today in the United States. The individual wires are hot dipped galvanized steel before weaving into the wire rope.

Today, all wire rope systems are mounted on small posts that readily fracture or deform when impacted by errant vehicles. All wire rope systems in the United States were low or no tension, that is, less than 2000 lb (8900 N) of tension in the wire ropes, until approximately 2000–2. A typical low-tension wire rope system is shown in Fig. 3.

Figure 3 Typical low-tension wire rope system. Source: National Academy of Science.

Figure 4 Roadside and median guardrails. Source: Elderlee used with permission.

High-tension systems, that is, 3,000 lb (13,360 N) of tension or greater, were introduced in the United States at the turn of this century. The systems were previously developed in Europe. High-tension systems are considered to perform better over time as they have residual capacity after impacts, that is, wire ropes are often still in position, for subsequent impacts. Additionally, sagging wire ropes are less of an issue in high-tension systems with large temperature swings. Most high-tension wire rope systems today use prestretched wire ropes that also tend to relax less through thermal cycling each year. Another positive feature of wire rope systems is vehicles are trapped within the system during accidents. This prevents secondary impacts that might occur when vehicles are redirected back into traffic on more rigid systems.

The most common RSB used in the United States is the w-beam guardrails system. This system is considered a semirigid RSB, stiffer than wire ropes but more flexible than concrete barriers. Typical guardrail deflections are approximately 3–5 ft. (0.9–1.5 m) under compliance crash testing conditions.

W-beam guardrails are used in both roadside and median applications and are installed on both weak and strong post. **Fig. 4** shows typical strong post installations for roadside and median.

The weak post system is most often installed on S3x5.7 posts that are spaced at 12 ft. 6 in. (3.8 m) on center and no offset blocks are used. Strong post guardrail systems are mounted on 6x8 wood posts or a W6x8.5 or W6x9 wide flange posts that are spaced 6 ft. 3 in. (1.9 m) on center. Most strong post systems employ either an 8 in. (200 mm) deep or 12 in. (305 mm) deep offset block to minimize wheel snag on the posts during impact. The w-beam rail elements are manufactured in both 12 ft. 6 in. (3.8 m) and 25 ft. (7.6 m) lengths and are fabricated from both 10- and 12-gauge sheet metals with the most common applications using 12-gauge. Pre-galvanized or hot dipped galvanized w-beams are used in most installations. Prior to 2000, most guardrail systems were mounted with the splices at the post and the top of the guardrail was approximately 27 in. (0.70 m) above grade. Vehicles, especially in the United States, have continued to get heavier with higher center of gravities. This has led to design modifications in the w-beam system. Top mounting height is currently recommended to be 31 in. (0.79 m) and the splices are moved to midspan to achieve a slightly greater redirective capacity.

Concrete barriers are the most expensive and rigid of all RSBs. The NCHRP Synthesis 244 Report states, “Although it is not clear exactly when or where the first concrete median barriers were used, concrete median barriers were used in the mid-1940s on US-99 on the descent from the Tehachapi Mountains to the central valley south of Bakersfield, California (Ray and McGinnis, 1997). This first generation of concrete barriers was developed to (a) minimize the number of out of control trucks penetrating the barrier, and (b) eliminate the need for costly and dangerous median barrier maintenance in high-accident locations with narrow medians” Clearly Caltrans was involved in this early version of what came to be known as the K-rail. In the 1950s concrete barriers were developed by the Stevens Institute of Technology, New Jersey, under the direction of the New Jersey Highway Department. Hence, the name New Jersey barrier was adopted. The first installed New Jersey Barrier was only 460 mm tall in 1955 and was subsequently increased in height to 810 mm in 1959 for improved performance.

In the 1970s research was undertaken at Southwest Research Institute to further improve the performance of the concrete safety shape that ultimately leads to the development of the F-shape. The name was derived from the research iterations conducted on variations to the New Jersey barrier. It was the sixth alternative identified in the research project, corresponding to the sixth letter of the alphabet, “F.” While similar in shape to the New Jersey barrier, the height of the lower slope was reduced by 75 mm, reducing the amount of climb that occurred when compared to the New Jersey barrier, improving vehicle stability. The New Jersey barrier and the F-shape are shown in **Fig. 5**.

Another variant of the New Jersey barrier was developed by the Ministry of Transportation of Ontario, the Ontario Tall Wall. The Ontario Tall Wall was 1070 mm tall with the bottom 75 mm embedded in the adjacent pavement. It was unreinforced and successfully crash tested with a 36,000 kg tractor trailer impacting at 85.3 km/h.

Figure 5 Concrete barrier shapes. Source: JJ Hooks used with permission.

Caltrans and the Texas Transportation Institute both developed Single Slope concrete barriers in the next evolution of concrete RSBs. Both of the systems have slopes of approximately 10 degrees in contrast to the upper slopes on the New Jersey and F-shape barriers of approximately 6 degrees. Caltrans design was slightly taller with a little less slope on the face creating a wider top on the barrier. These designs were selected to accommodate future pavement overlays without changing vehicular interaction with the face of the barriers. The removal of the lower, flatter slope improved vehicle stability during crashes.

Concrete RSBs are installed in both temporary and permanent installations. Temporary installations are often used in construction areas on the roadway, otherwise known as work zones. Temporary concrete barriers, also known as portable concrete barriers, are usually connected to one another but are only pinned or fixed to the roadway when deflections must be limited. Concrete RSBs in permanent locations are often cast in place and integral with the roadway providing anchorage to the system and minimal displacement occurs when impacted.

If temporary systems are unanchored, deflection is controlled by connection type and size of barriers connected. Longer and taller barriers weigh more and provide more resistance during impact. If the connection between barriers is loose or highly flexible, deflections increase. Conversely, tight or stiff connections tend to transfer more load to adjacent barriers, thus reducing deflections. As discussed previously, deflections tend to reduce accelerations to occupants of errant vehicles but, if workers are present behind a temporary barrier, deflections may cause injuries to those workers. There are a number of both proprietary and nonproprietary connection types used in the field today. Loose or flexible connections are easier to install, allowing for more rapid deployment in most cases.

Acknowledgment

This work was completed with financial support from Safe Roads Engineering, Stouffville, Ontario. Editorial review by Mr. Ben Powell is greatly appreciated.

Biography

Dr. Dean C. Alberson has served most of his career at the Texas A&M Transportation Institute (TTI). When he retired from TTI, he was a Senior Research Engineer and Program Manager of the Crashworthy Structures Program in the Roadside Safety Division. He is a registered professional engineer in the State of Texas. He obtained his PhD in Civil Engineering Structures at Texas A&M University.

Introduction

The management of the safety of road transportation varies by country in western economies. Some countries are federations of provinces, states, and/or territories which have roles and responsibilities for the federal government and for other levels of government. Typically, federal governments address road safety issues which are common across the country such as motor vehicle regulations and standards for new and imported vehicles, motor carrier transportation, and criminal laws related to road safety (e.g., alcohol and drug impairment, dangerous driving, etc.). Lower levels of government usually manage driver licensing, vehicle registration, and road infrastructure. However, some road safety issues are handled by both the federal governments and the state/provincial governments such as road safety research, including collision data gathering, and policy and program development. In addition, there are oversight agencies which investigate collisions involving road vehicles, and make recommendations for improvements regarding safety (e.g., US National Transportation Safety Board).

Some countries have road transportation research institutes which conduct and/or foster road safety research. Some of these are established at the national level (e.g., Transport Research Laboratory in the United Kingdom, which is now privatized, SWOV in the Netherlands). In other countries, research is conducted within governmental agencies (e.g., US Department of Transportation, Transport Canada) or supported by funding such as the Transportation Research Board in the United States. A considerable amount of research is conducted in university-based institutes such as the University of Michigan Transportation Research Institute. There are also industry-based institutes such as the Insurance Institute for Highway Safety in the United States which is supported by the vehicle insurance industry. While there are a number of governmental, quasi-governmental, and nongovernmental organizations (NGOs) involved in various aspects of road safety management, it is debatable how coordinated these activities are. With so many separate organizations, there is a risk of duplication of activities or some issues may fall between the fractured responsibilities.

The purpose of this chapter is to describe how road safety is managed in selected countries including Australia, Canada, the Netherlands, Sweden, the United Kingdom, and the United States. **Table 1** shows the country profile for each of the subject countries ([International Transport Forum: Road Safety Annual Report, 2019](#)).

It should be noted that vehicle and road regulations are not always within the sole authority of the government. An example would be Sweden, and the Netherlands, which has regulations that all members are required to comply with. Another example would be Canada, which has limited influence with respect to vehicle safety standards given the relative size of the United States versus Canada market. These outside influences must be considered when examining the safety records of individual nations.

Australia

Australia is a federal state consisting of a federal government and seven state and territorial governments. The Australian Government is responsible for regulating safety standards for new vehicles, and for allocating infrastructure resources, including those for safety, across the national highway, and local road networks. State and territorial governments have primary responsibility for funding, planning, designing, and operating the road network, managing vehicle registration and driver licensing systems, and enforcing road user behavior.

The federal Department of Infrastructure, Regional Development, and Cities has a range of functions that support the Australian Government's role in road safety. These include: administering vehicle safety standards for new vehicles, administering the National

Black Spot Program and other road funding, administering the keys2drive program for new drivers, producing national road safety statistics, and coordinating the *National Road Safety Strategy (NRSS) 2011–20* ([Australian National Road Safety Strategy, 2011–2020](#)). The NRSS, now overseen by the Transport and Infrastructure Council, represents the commitment of federal, state, and territorial governments to an agreed set of national road safety goals, objectives, and actions. It has the specific target of reducing Australia's annual number of road deaths and serious injuries by at least 30% by 2020.

The number of road fatalities in 2016 was 9% lower than the 2008–10 baseline and the fatality rate per 100 million vehicle kilometers traveled was 18% lower. Significant reductions were observed in single vehicle fatalities (–12%), fatal crashes involving young drivers/riders (–25%), fatally injured drivers with a blood alcohol concentration (BAC) over the 0.05 limit (–40%) and crashes involving heavy vehicles (–17%).

A recently published NRSS 2011–20 implementation status report identified areas where progress was being made as well as areas needing improvements.

All jurisdictions have integrated Safe System principles, as seen in [Table 2](#), into road safety project planning, and road authorities are continuing their efforts to increase understanding and acceptance of this accountability throughout their organizations and with local commitment to Safe System principles. All levels of government have assessed risks on their road network and refocused their road investment program on higher risk road sections while balancing safety and mobility objectives.

All jurisdictions are continuing to work to implement safer speeds in rural and urban environments, particularly on roads with a high-crash risk. For example, the state of Victoria has introduced lower speed limits as part of several Safer System Roads Infrastructure Programs (SSRIP), which include high-speed rural roads and local streets. Compliance with speed limits is also being improved. For example, Queensland and Western Australia (WA) are piloting and implementing point-to-point (average speed) camera enforcement. WA's trial has been evaluated and the site is continuing as an enforcement zone. A number of Australian Design Rules for vehicles have been promulgated by the federal government including pole side impact occupant protection standards for

Table 2 Four Principles of the Safe Systems Approach (SSA)

<i>Principle</i>	<i>Description</i>
Ethics	Human life and health are paramount and take priority over mobility and other objectives of the road traffic system (i.e., life and health can never be exchanged for other benefits within the society)
Responsibility	Providers and regulators of the road traffic system share responsibility with users
Safety	Road traffic systems should take account of human fallibility and minimize both the opportunities for errors and the harm done when they occur
Mechanisms for change	Providers and regulators must do their utmost to guarantee the safety of all citizens; they must cooperate with road users; and all three must be ready to change to achieve safety. It is recognized that Canadian jurisdictions will implement the SSA in a manner that is appropriate to their traffic environment

new vehicles (i.e., a test of a vehicle's ability to protect the occupant's head in the event of a side impact with a narrower object), electronic stability control for new heavy vehicles, and anti-lock brake systems for new motorcycles.

Austrroads is an association of road authorities whose purpose is to support its member organizations to deliver an improved Australasian road transport network that meets the future needs of the community, industry, and economy. To achieve this purpose, Austrroads undertakes leading-edge road and transport research underpinning policy development and publishes guidance on the design, construction, and management of the road network and its associated infrastructure. There are several universities that conduct road safety research such as the Monash University Accident Research Centre.

The state of Victoria has a government-owned insurer called the Traffic Accident Commission (TAC), the role of which is to promote road safety, improve the state's trauma system and support those who have been injured in collisions. It is funded through a TAC charge which is a component of the payment made by Victorian motorists when they register their vehicles each year. TAC has established a Toward Zero vision and adopted the Safe System Approach in order to achieve this vision. It conducts awareness campaigns on alcohol and drug-impaired driving, driver distraction by cell phones, speeding, fatigued driving, among others.

Canada

Canada is a federation consisting of a national government and 13 provincial and territorial governments. At the federal level, the Multi-Modal and Road Safety Programs Directorate is located within Transport Canada (TC). Under the authority of the *Motor Vehicle Safety Act*, TC is primarily responsible for the researching and promulgating of motor vehicle standards and regulations, as well as enforcing them through detailed compliance testing, and through defect and collision investigations. These vehicle standards and regulations are administered at the national level and the vehicles are labeled by the manufacturers with the National Safety Mark.

TC also gathers collision-related data from the provincial and territorial governments in order to update the National Collision Database (NCDB) annually and conducts research on road user behavior in order to assist jurisdictions to identify road safety-related issues and their magnitude and nature (e.g., distracted driving, drug-impaired driving, vulnerable road users' safety, etc.).

TC is also responsible for the safety of inter-jurisdictional motor carrier transportation (i.e., movements of heavy vehicles and buses across international and provincial/territorial borders) under the authority of the *Motor Vehicle Transport Act*. TC develops national regulations and standards to promote vehicle safety (e.g., electronic stability control), driver safety (e.g., hours of service regulations), and the management of carrier operations (e.g., electronic logging devices).

It should be noted that the provincial and territorial jurisdictions are responsible for the intra-jurisdictional movement of carriers. Efforts are made to harmonize these regulations with those of the national government but they are not always the same creating difficulty for some carriers operating between jurisdictions. There is also a National Safety Code (NSC) which consists of a number of standards which motor carriers are expected to follow. The NSC was developed jointly by the federal and provincial/territorial governments through the Canadian Council of Motor Transport Administrators (CCMTA), a not-for-profit national body which promotes cooperative road safety activity across the country. The NSC includes 16 standards for maintenance and periodic inspections, as well as driver training and licensing, drivers' hours of service, driver medical fitness, load securement, among others.

The 13 provinces and territories also play a major role in promoting road safety in Canada. They are responsible for the registration of all vehicles operating on public roads, the licensing of all classes of drivers, driver records, and driver improvement, traffic law enforcement on highways and the construction, maintenance, and operation of highways, as well as road safety-related legislation, policy, and regulations.

The jurisdictional governments are organized in different ways to manage road safety. In four provinces (British Columbia, Saskatchewan, Manitoba, and Quebec), there are Crown corporations that provide comprehensive compulsory auto insurance, driver licensing, and vehicle registration services. They also conduct road safety and loss management programs to reduce traffic-related deaths, injuries, and crashes. Road safety-related legislation is usually handled by government departments which works in partnership with law enforcement agencies, service providers, professional organizations, other government agencies in the development of legislation, regulations, policy, and programs.

In other jurisdictions, all aspects of road safety are managed by departments of transportation but in some cases, driver and vehicle licensing are handled by government service agencies or public safety offices. Vehicle insurance should be dealt with by private with private companies in these jurisdictions. In all 13 Canadian jurisdictions, the construction, operation, and maintenance of the highways are the responsibility of the jurisdictional departments of transportation.

Most large municipalities have transportation departments which are responsible for constructing, operating, and maintaining local streets. Typically, highways/expressways which run through municipalities are managed by the province. Some municipalities have their own road safety offices (e.g., Ottawa, Toronto, Edmonton).

Traffic law enforcement also varies by jurisdiction. Larger municipalities have their own police services. Two jurisdictions have provincial police forces (Ontario and Quebec) which perform traffic enforcement on highways and provide policing in smaller municipalities. The other provinces and territories have contracts with the Royal Canadian Mounted Police, the national police force, to provide enforcement on highways and in smaller municipalities.

The Council of Ministers responsible for Transportation and Highway Safety meets annually to address a variety of road safety issues (e.g., National Highway System, driver safety issues and motor carrier safety etc.). The members of this Council are federal, provincial, and territorial ministers who discuss common interests and goals.

Table 3 Road safety strategy 2025 safety matrix of risk groups and contributing factors

		Contributing factors								
		Alcohol impaired driving	Drug impaired driving	Distracted driving	Fatigue impaired drivers	Speed and aggressive drivers	Unrestrained occupants	Environmental factors	Road infrastructure	Vehicle factor
Risk group	Young/Novice driver									
	Medically at risk drivers									
	Vulnerable Road Users									
	Commercial drivers									
	High risk drivers									
	General population									

There are two not-for-profit quasi-governmental organizations which work to coordinate road safety activities across Canada, namely the Canadian Council of Motor Transport Administrators (CCMTA) and the Transportation Association of Canada.

CCMTA has a Board of Directors including senior-level representatives of all federal, provincial, and territorial governments. CCMTA is the custodian of Canada's latest strategy Road Safety Strategy (RSS) 2025, the vision of which is Toward Zero: The Safest Roads in the World. This vision is not a target to be achieved by a certain date; it is aspirational.

Under RSS 2025, each jurisdiction is responsible for identifying their specific road safety issues and developing programs and other interventions to improve road safety. To assist jurisdictions, an inventory of proven and promising countermeasures has been developed by CCMTA based on previously conducted evaluations of these measures in Canada or elsewhere. Jurisdictions are encouraged to implement these measures.

Table 3 shows the safety matrix of risk groups and contributing factors.

The Transportation Association of Canada is a not-for-profit, national technical association dealing with road and highway infrastructure and urban transportation. Membership includes all levels of governments, private sector companies, academic institutions, and other associations. The goal is to provide a neutral, nonpartisan forum to share ideas and information, build knowledge, and pool resources in addressing transportation issues and challenges. Transportation Association of Canada does not set standards but publishes guidelines for planning, design, construction, management, operation, and maintenance of road, highway, and urban transportation infrastructure systems and services.

While there are no road safety institutes in Canada, there are universities which conduct research on road safety (e.g., University of Montreal, University of Toronto, Western University, University of British Columbia). In addition, there are also research institutes which are not-for-profit (e.g., the Traffic Injury Research Foundation in Canada) which conduct contract-based road user research. There are also a number of NGO's which promote road safety such as Mothers Against Drunk Drivers Canada, Arrive Alive Drive Sober, and the Canadian Automobile Association.

The Netherlands

The Netherlands has a central government as well as provincial and local governments. The creation and monitoring of National Road Safety Strategy, the setting of targets, and the development of the RS programs involve the Ministry of Infrastructure and the Environment (MIE), the provinces, urban regions, Rijkswaterstaat (i.e., water boards) and municipalities, Safe Traffic Netherlands (VVN) and the Institute for Road Safety Research (SWOV). Improvements in road infrastructure are managed by the MIE, the Rijkswaterstaat and SWOV. Vehicle improvement is administered by the MIE. The improvement of road user education is led by the MIE but each province has a Regional Road Safety Body which provides information and education to the public. Publicity campaigns are conducted by the MIE while enforcement of road traffic laws is dealt with by the Ministry of Security and Justice, the National Traffic Prosecution Team, and the local police. Much of the road safety research in the Netherlands is carried out by SWOV.

The Netherlands follows a bottom-up approach such that ambitious but realistic targets are defined and updated on the basis of expected trends in casualties ([European Road Safety Observatory: Road Safety Country Overview-Netherlands, n.d.](#)). The prevailing policy plan (Road Safety Strategic Plan 2008–20, *From, for, and by everyone*) has separate targets for fatalities and serious injuries. Every four years, it is reviewed to determine whether the targets for fatalities and serious injuries are still achievable and whether the current policy strategy should be adjusted. This process starts with forecasts for the numbers of fatalities and serious injuries based on a two-step approach. First, extrapolation of past casualty rate trends for different road user categories are combined with forecasts on distances traveled (using a lowest and highest forecast scenario). Secondly, this extrapolation is corrected for changes in road safety policies based on the assumption that known changes in policies do not allow for extrapolation of past trends.

Table 4 Five principles of sustainable development

<i>Principle</i>	<i>Description</i>
Functionality	Related to roads: ideally, road sections and intersections have only one function for all modes of transport (mono-functionality): a traffic flow function or an exchange function
(Bio)mechanics	Ideally, traffic flows and transport modes are compatible with respect to speed, direction, mass, size, and degree of protection supported by the design of the road, the road environment, the vehicle, and, where necessary, additional protective devices
Psychologics	The design of the traffic system is well-aligned with the general competencies and expectations of road users, particularly older road users. The information from the traffic system is perceivable, understandable ("self-explaining"), credible, relevant and feasible. Road users are capable of carrying out their traffic task and adjust their behavior according to the task demands for participating in traffic safely under the prevailing circumstances
Effectively allocating responsibility	Responsibilities are allocated and institutionally embedded in such a way that they guarantee a maximum road safety result for each road user and optimally integrate with the inherent roles and motives of road users (i.e., road users follow the rules and set a good example for children and teenagers). Forgiving traffic systems ensure that road users will not be punished for their errors and weaknesses by crashing and sustaining serious injuries
Learning and innovating in the traffic system	Responsibilities are allocated and institutionally embedded in such a way that they guarantee a maximum road safety result for each road user and optimally integrate with the inherent roles and motives of road users (i.e., road users follow the rules and set a good example for children and teenagers). Forgiving traffic systems ensure that road users will not be punished for their errors and weaknesses by crashing and sustaining serious injuries

The Netherlands has had a Sustainable Road Safety approach since 1992 and it has been found to have a benefit-cost ratio of 3.6: 1. The vision of Sustainable Safety is to have an optimal approach to improve road safety in the Netherlands. A sustainably safe road traffic system prevents road deaths, serious road injuries, and permanent injuries by systematically reducing the underlying risks of the entire traffic system (i.e., Safe System Approach). Human factors are the primary focus: by starting from the demands, competencies, limitations, and vulnerabilities of road users, the traffic system can be realistically adapted to achieve maximum safety.

The current version of the Sustainable Safety Vision is characterized by five road safety principles adapted from the previous principles and strengthened with new insights, thereby providing a basis for specific solutions. The principles are explained in [Table 4](#).

Concerning the road design principles, vulnerable road users (pedestrians and cyclists in particular) and the competence of older road users are the more explicit foci now. The latest edition of the Sustainable Safety vision pays greater attention to cyclist crashes not involving motorized vehicles; responsibility is emphasized with respect to the role and potential actions of stakeholders in realizing an inherently safe road traffic system; in-depth analysis of all fatal road crashes to learn from the things that still go wrong; a pro-active and risk-based approach; and using both crash statistics and road safety performance indicators or surrogate safety measures as safety indicators as a basis for action.

For a number of years, road safety in the Netherlands has been in decline: while road deaths are no longer decreasing, serious road injuries continue to increase. The safety of cyclists is a specific problem, not only in terms of road deaths, but also in terms of serious road injuries. Four developments could perhaps explain why the Dutch performance has deteriorated: a lack of political priority for road safety, reduced government budgets for road safety, a decentralization of "power" from national to regional and local governments, and a lack of priority in the police forces for traffic safety, combined with a substantial increase in traffic, especially by cyclists, and an increased use of mobile phones resulting in distraction.

However, recently, a manifesto supported by about 30 organizations was published in 2017 and a new federal government has included road safety in its program. In addition, the Dutch Parliament has put more pressure on the government to address road safety and the new Transport Minister has supported this.

Sweden

Sweden has a national government as well as several provincial governments ([European Road Safety Observatory: Road Safety Country Overview-Sweden, n.d.](#)). The federal Swedish Transport Administration (Trafikverket) is the government agency responsible for the long-term planning of the transport system. Trafikverket is also in charge of the state road network and road safety policies. Other agencies involved include the Ministry of Enterprise and Innovation, which is responsible for the road infrastructure and the monitoring of road safety development and the Swedish Transport Agency, which is responsible for vehicle safety improvement and road user education and publicity.

Sweden was the first country to adopt the Vision Zero philosophy as a government policy in 1997 putting people first and focusing mainly on reducing collisions that can lead to fatalities or lifelong injuries. This vision's long-term objective is that no one should be killed or seriously injured in traffic and that the design, function, and use of the road transport system shall be adapted to the standards this vision requires. Responsibility for road safety is shared between individual transport system users and "system designers" (i.e., automotive industry, lawmakers, and infrastructure owners). This vision is being pursued by following the Safe System Approach whereby a road system should be designed so as to minimize the harm of potential human errors. Municipalities, companies, organizations, and authorities are collaborating to reach this ambitious goal. If road transport system users do not follow

the rules for reasons such as lack of respect, knowledge, acceptance or capacity or if personal injuries occur in a crash, the system designers must take further measures to prevent deaths and serious injuries.

A methodology was developed in Sweden called OLA: Objective data, List of solutions/actions, and addressed Action Plans. The OLA methodology was used when an analysis of collision statistics revealed an important road safety issue (e.g., too many moped drivers being killed). The aim of OLA was to have different stakeholders work together to solve a road safety issue. The use of this methodology has had an important impact as it committed stakeholders to implement solutions and not just recognizing a problem. Today, OLA is used as a complement to the Management by Objectives framework.

Some of the measures that have been adopted in Sweden include 2 + 1 roads which separate vehicles on highways with a cable on the centerline and replacing signalized intersections with roundabouts. Other measures focus on changing the behavior of drivers (e.g., installing speed cameras, building narrower roads and wider sidewalks in cities so that drivers are forced to keep a slower pace in busy areas, a .02 Blood Alcohol Concentration (BAC), random alcohol breath tests, encouraging car manufacturers to build safer vehicles with built-in features like loud signals that are only switched off when passengers buckle up).

Sweden has a national police force but most of the traffic law enforcement is conducted by local police services. This enforcement activity is overseen by the Swedish National Police Board. Sweden has recently renewed its commitment to Vision Zero.

Sweden has adopted the following target: the number of fatalities in road traffic shall be halved and the number of serious injuries shall decrease by one quarter between 2007 and 2020. In 2007, a total of 471 people died in traffic crashes in Sweden but that figure is now down to 252 in 2017, a reduction of 46.5%.

United Kingdom

The United Kingdom is a unitary state without states or provinces, although it does have local authorities and Scotland and Northern Ireland have some road-related authorities ([European Road Safety Observatory: Road Safety Country Overview-United Kingdom, n.d.](#)). The main central government departments and agencies with road safety responsibilities are transport, highways, health, justice, policing, and health and safety. There is a strong interdepartmental coordination to achieve agreed upon targets, orchestrated by the lead agency, the Department for Transport (DfT). The Secretary of State for Transport has responsibility on behalf of the government for the safety of the road traffic system in England and Wales. In Scotland, it is the Transport Minister and in Northern Ireland, it is the Minister of the Environment.

The DfT includes the Roads, Devolution, and Motoring Group (RDM) that consists of the Road Safety Standards and Services Directorate (RSSS) which is the lead on road safety policy and the coordination of road safety activity. Within the RSSS, the Road User Licensing Insurance and Safety Division (RULIS) is responsible for the development of road safety strategy. However, other divisions of RDM have responsibilities that are relevant to road safety policy such as International Vehicle Standards, Freight Operator Licensing, Active Accessible Travel, the latter being where cycling and pedestrian safety policy sits, Local Transport Infrastructure and national road investment. The RDM agencies responsible for Driver and Vehicle Standards (DVSA), Driver and Vehicle Licensing (DVLA), and Vehicle Certification (VCA) play key roles with regard to driver training and testing and vehicle roadworthiness standards. Responsibility for safety on the strategic roads network rests with Highways England.

The Department of Health, supported by a range of agencies including National Health England and Public Health England, has the mission of “helping people to live better for longer.” It has a core, strategic responsibility for road injury surveillance in the health sector, emergency medical response, major trauma care, the rehabilitation of road crash victims, and road injury prevention.

Local authorities have a general duty under the Road Traffic Act, 1988 to carry out road collision studies and a range of ensuing, appropriate preventative actions. Traffic law enforcement is carried by local police services with the Traffic Commissioners for Great Britain serving as an oversight body.

The United Kingdom has adopted the Safe System Approach in its national strategy to reach its vision of zero fatalities and serious injuries. In 2011, an independent evaluation of the Delivery of Local Road Safety commissioned by the Department for Transport found that “the existence of national targets had provided a useful stimulus to local partnership working.” However, post-2010, there was a change in focus away from national casualty targets. The review found widespread concern among most stakeholders including several key agencies about the absence of explicit national goals and interim targets and the safety performance monitoring associated with these targets that was having a negative impact on the focus on results and levels of activity, both nationally and locally. The lack of a national target had an impact on the priority given to road safety locally and its ability to compete for scarce funds.

In 2018, the DfT commissioned a Road Safety Management Capacity Review which examined institutional management functions, road safety coordination among the various partners, legislation, funding, and resource allocation, road safety promotion, monitoring, and evaluation and research. This review identified the strengths of the UK’s Road Safety Management to be a well established information sharing structure at the national level bringing together key road safety partners and mature, local road safety partnerships. New regional road safety coordination for the strategic road network (SRN) was being developed by Highways England.

Weaknesses in road safety management included the absence of a national road safety performance framework for the short and long-term resulting in a lack of focus and cohesion in coordination efforts; interdepartmental coordination was insufficient to ensure road safety objectives and the Safe System Approach were embedded in the policies of responsible agencies; little engagement in road safety delivery by key national Departments; vertical coordination between central and local government was present but

insufficient when compared with identified good practice; multisectoral involvement was reported to be falling away in local road safety partnerships.

There were many recommendations made in this review including a call for stronger leadership by the central government and a new national road safety coordination hierarchy to strengthen joint activity across the central government and between this government and local governments. This leadership would comprise a Minister-led, high-level Road Safety Strategic Partnership Group (RSSPG) with senior representatives from central and local government, police and other key road safety partners which would be focused on agreed upon priorities within a new road safety strategy and steering and overseeing the delivery of a Safe System Approach and quantified objectives.

The review also recommended that a new national road safety performance framework should be created which would set out the long-term Safe System/Toward Zero goal of working toward the ultimate prevention of deaths and serious injuries, set interim quantitative targets to 2030 to reduce the numbers of deaths and serious injuries, and set measurable, intermediate outcome objectives for activities to 2030 which are directly related to the prevention of death and serious injury. In order to achieve these targets, the strategy should focus on increasing compliance with speed limits on different road types, reducing average speeds on different road types, increasing the level of seat belt and child restraint use, increasing the level of helmet use for two-wheeled vehicle users, reducing driving while impaired by alcohol and drugs, increasing compliance with in-car telephone use rules, increasing the safety of the SRN and main road network to the highest International Road Assessment Programme (iRAP) star rating, and increasing the safety quality of the new car fleet to the highest Euro NCAP rating.

Subsequent to this review, a British Road Safety Statement (BRSS) was published by the national government with a commitment to invest further in continuing road safety activity but endorsing devolution and local decision-making rather than centralized national targets for the United Kingdom. The government's commitment to embedding a Safe System Approach nationally is evident in a safety performance framework for long-term goals and interim targets which are set for the SRN and in the setting up of a Safer Roads Fund. The objectives of the framework are that by 2040, the number of people killed or seriously injured on the SRN should approach zero; by 2020, the aim is for a 40% reduction in fatalities and serious injuries compared to a 2005–09 baseline, and by 2020 more than 90% of travel on the SRN should be on roads with an iRAP rating of 3.

The major public awareness campaign on road safety-related issues is the Think! Campaign, which is managed by the DfT. The campaigns address, alcohol and drug impaired driving, distracted driving, speeding, among others.

Some of the road safety interventions are managed at the local level with support from the DfT. There are also NGOs such as Brake and the Royal Society for the Prevention of Accidents, both of which promote road safety awareness and knowledge.

It is unclear how Brexit and the changing relationship with Europe may impact road safety in the United Kingdom.

United States

The United States is a federated country with a national government and 50 states. The national government has a Department of Transportation (US DoT) that includes the National Highway Traffic Safety Administration (NHTSA). This organization is responsible for the promulgation of motor vehicle safety regulations and their enforcement, as well as research related to vehicle safety and road user behavior and the development of road safety education programs which are supported by regional offices. It maintains a number of national databases including among others, the Fatality Analysis Reporting System (FARS) which is a census of all fatal collisions in the United States and the National Automotive Sampling System (NASS) General Estimates System (GES) which contains information on a representative sample of collisions that occur in the country. NHTSA also supports the New Car Assessment Program (NCAP) which provides consumers with safety ratings of new vehicles based on existing standards. The more stars given a vehicle, the safer it was found to be in testing. The Volpe National Transportation Systems Center conducts vehicle safety research at its facility. NHTSA also publishes the report Countermeasures that Really Work which provides guidance regarding which safety measures could be adopted (Richard et al., 2018).

The US DoT's Federal Motor Carrier Safety Administration (FMCSA) regulates the commercial vehicle (trucks and buses) industry in the United States by ensuring safety in motor carrier operations through enforcement of safety regulations, targeting inspections of high-risk carriers and commercial motor vehicle drivers, improving safety information systems and commercial motor vehicle technologies, strengthening commercial motor vehicle equipment and operating standards, and increasing safety awareness.

The Federal Highways Administration (FHWA) in US DoT supports state and local governments in the design, construction, and maintenance of the nation's highway system. Through financial and technical assistance to state and local governments, the FHWA ensures that America's roads and highways continue to be safe. The FHWA includes an Office of Safety which is responsible for highway designs and technologies that improve safety performance. Major program areas and initiatives include roadway departure, roadside hardware, retro-reflectivity, roadside safety, pavement safety, roadway systems design, intersection safety, Road Safety Audits, speed management, pedestrian/bicyclist safety, local and rural roads safety, and safety countermeasure analysis. Also, included are the Highway Safety Improvement Program (HSIP), Strategic Highway Safety Plans (SHSPs), High-Risk Rural Roads, driver penalty programs and monitoring, data analysis and tools, and coordination with external and internal safety stakeholders, partners, and advocates.

The National Transportation Safety Board is independent from the government and investigates major collisions in all modes including those involving commercial motor vehicles and occasionally light-duty vehicles. Their investigations often include recommendations to the federal government regarding how to prevent such collisions in the future.

In some of the states, road safety is managed by departments of transportation which license drivers and register vehicles, construct, operate, and maintain highways, and conduct research and policy and program development on road safety. In other states, the functions are split between the department of transportation and the department of motor vehicles. Each state has its own set of traffic safety laws. Traffic law enforcement is typically managed by municipal or state police services. Smaller communities are policed by Sheriff's Departments.

The American Association of Motor Vehicle Administrators (AAMVA) is a not-for-profit, nongovernmental organization, which develops model programs in motor vehicle administration, law enforcement and highway safety. AAMVA represents the state and jurisdictional officials in the United States and Canada who administer and enforce motor vehicle laws. AAMVA's programs encourage uniformity and reciprocity among the states and provinces. The association also serves as an information clearinghouse in these areas and acts as the international spokesperson for these interests. The association also serves as a liaison with other levels of government and the private sector. Its research and development activities provide guidelines for more effective public service. AAMVA's membership also includes associations, organizations and businesses that share an interest in the association's goals.

The Governors' Highway Safety Association (GHSA), whose board consists of state Governor appointed directors of traffic safety commissions, is organized to assist its members in implementing the highway safety programs of the Governors of several States, the District of Columbia, and territories to aid them in the development of policies consistent with the needs and goals of these states (e. g., study all problems connected with highway safety; to develop technical, administrative, and educational highway safety standards, to cooperate with other agencies in the consideration and solution of highway safety problems, etc.

The Insurance Institute for Highway Safety, which is funded by the insurance industry, also conducts a vehicle safety rating program based on common crash configurations and it also supports research on various aspects of road safety through special projects.

There are numerous university-based research institutes in the United States such as the University of Michigan Transportation Research Institute, the Virginia Technology and Transportation Institute, and the University of North Carolina Highway Safety Research Center, to name a few which conduct road safety-related research.

Although there is no formal road safety strategy in the United States, in recent years, NHTSA and many state and local transportation agencies have begun to embrace various versions of Safe System/Vision Zero strategies. NHTSA for example, has documented progress toward zero deaths on a state-by-state basis. US DoT, NHTSA, FHWA, FMCSA are all part of a Road to Zero coalition focused on strategies to end-vehicle fatalities by 2050.

Several federal programs mandated at the state level provide an organizational context for the deployment of proven countermeasures and for supporting the principles of a Safe Systems/Toward Zero Deaths approach. A major example is the Strategic Highway Safety Plan (SHSP). Each state is required to develop a coordinated plan for reducing fatalities and serious injuries on public roads. The SHSP for each state convenes the major stakeholders for that state and develops a plan for coordination of efforts in the areas deemed most critical for that state. The SHSP is a requirement of the Highway Safety Improvement Program (HSIP) (23 USC § 148) which provides funding to states.

Conclusion

In the 2018 Annual Report of the International Transport Forum and the Organisation for Economic Cooperation and Development, the change in the number of road deaths is reported for member countries from 2010 to 2016. According to this report, the changes for the six countries included in this review of road safety management can be seen in [Table 5](#). Clearly, despite the similarities in road safety management approaches, they have not resulted in the same outcomes for all countries.

Andras Varhelyi, a professor in Transport and Roads at Lund University in Sweden, has reviewed a number of articles on road safety management and identified several steps that should be followed in order to effectively manage road safety:

1. Define the burden and nature of road casualties;
2. Gain commitment and support from decision makers including politicians;
3. Establish a Road Safety Policy;
4. Define institutional roles and responsibilities;
5. Identify road safety problems;

Table 5 Change in road deaths, 2010–16

Australia	–4.1%
Canada	–15.2%
Sweden	+ 1.5%
The Netherlands	– 1.7%
United Kingdom	– 2.4%
United States	+13.5%

6. Set Road Safety Targets;
7. Formulate Strategy and Action Plan;
8. Allocate responsibility for measures;
9. Ensure funding;
10. Apply measures with known effectiveness;
11. Monitor performance;
12. Stimulate research and capacity building.

A number of international resources are available to assist in the management of road safety. The International Organization for Standardization (ISO 39001) endorses the Plan-Do-Check-Act road safety strategy. The United Nations has a number of working parties dealing with road safety and vehicle regulations. The Global Forum for Road Traffic Safety (WP.1) deals with harmonization of traffic rules by overseeing a number of UN conventions to guide member nations and the World Forum for Harmonization of Vehicle Regulations (WP.29) is tasked with developing a uniform system of vehicle safety regulations.

The United Nations Road Safety Collaboration is an informal forum to discuss and share road safety issues to facilitate international cooperation and to strengthen global and regional coordination among UN agencies. In addition, the World Health Organization is responsible for the production of the Global Status Report on Road Safety, the latest addition being published in 2018. It also coordinates the Decade of Action on Road Safety which is an international effort to improve road safety in all countries.

Six countries of varying sizes and political systems have been presented to identify different safety systems and how they are applied in these countries. These systems are very much a part of the political, fiscal, and social fabric of the country but a number of key points emerge; the need for good data to define the problem and track progress, leadership, the setting of specific short and long-term targets, cooperation among different key stakeholders in road safety and that financing road safety has significant social, health, and fiscal benefits.

Road safety is an important social, financial, and economic issue and as such, improvements in fatality rates may differ across time in developing countries based on changing rules of the roads, enforcement levels, vehicle safety, medical treatment and public attitudes respecting safety. All of these areas must be considered to continually improve the fatality rate in a given jurisdiction.

Biographies

Paul Boase graduated from York University in Toronto with BA in Sociology/Psychology in 1979. In 1982, he graduated from the University of Toronto with Masters Degree in Psychology.

In 1987, he joined the Ministry of Transportation and Communications Ontario as Assistant Research Officer, and in 1990, was promoted to Senior Research Analyst. In this capacity, he worked on the annual collision statistics as well as a number of safety-related projects such as graduated licensing, administrative license suspension and photo radar. In 1999, Paul joined Transport Canada as Chief, Road Users where he is responsible for research related to road user behavior.

Current affiliations include: Board of Directors of the Canadian Association of Road Safety Professionals (CARSP). Member of the Road Safety Research and Policy Committee of the Canadian Council of Motor Transport Administrators (CCMTA).

Brian Jonah is an independent road safety consultant working in Ottawa. He retired from the Road Safety Directorate of Transport Canada in 2008 where he had been the Director, Road Safety Programs responsible for collision data collection and analysis, road user and road infrastructure research, the development of road safety related policy and programs, and communication with the public.

He has a Ph.D. in Social Psychology from Western University in London, Ontario. He has worked over the past 40 years on road safety research, vehicle safety regulation, and policy and program evaluation, with particular emphasis on alcohol and drug impaired driving, seat belt use, risky driving, distracted driving, and young drivers.

He is a member of the Board of the Canadian Association of Road Safety Professionals and is a Past President of the association.

Overview of Various Road Conditions

Generally speaking, road pavements are designed and built to provide comfortable, smooth, and safe travel for its service life, which is typically about 20–30 years. During this service time, various physical conditions and structural changes occur in roads. The main reason for this change is that, a roadway experiences complex environment throughout its life, in addition to bearing load-induced stresses from repeated traffic loading. Some major chemical compounds or environmental factors interacting with road materials are atmospheric oxygen, dissolved oxygen, UV radiation, and hundreds of other known and unknown solid, liquid, and gaseous compounds. As a consequence of the interactions between road materials and surrounding environmental factors, the road pavement loses its vital engineering properties over time. Often the deteriorated road conditions affect the travel and safety performance of roads. Under the effect of adverse winter events, snow and ice can also significantly affect road conditions. Transportation performance and road safety can be improved by improving roadway conditions. The first step toward this is the understanding on how various road conditions and distresses evolve.

Figure 1 Rutting distress in a roadway. *Source: Author.*

Spring and Summer Road Conditions—Surface Distresses and Road Safety

Pavement Surface Distresses

When designed and built properly, a road pavement has a smooth, continuous, and distress-free surface. Because of the negative effects of various factors including traffic loading and environmental factors, a pavement deteriorates which can result in a distorted, disintegrated, or cracked pavement surface (Garber and Hoel, 2015). The Distress Identification Manual for the Long-Term Pavement Performance Program developed by the Federal Highway Administration of the United States has summarized these distresses for asphalt and Portland-cement concrete roadways and provides detailed explanations of their occurrences (Miller et al., 2014). For example, for asphalt roadways (worldwide, over 90% of our roads are surfaced with asphalt pavements), they include rutting, cracking, patching and potholes, polished slippery surfaces, and miscellaneous distresses. Numerous studies have indicated that these distresses have moderately to strong relation with road safety.

Rutting

Rutting is a major form of road distress, which refers to the vertical depression on the road surface along the wheel paths (Fig. 1). Rutting can occur as a result of pavement being plastic and depressed by heavy loads, or by the grinding effect of studded tires. The former occurs due to the excessive deformation occurring in the pavement structure stemming from issues with the pavement mix design. For example, when excessive air void content is present in the paving mixture, one-dimensional densified rutting occurs. When aggregate mix selected does not provide adequate shearing resistance through the internal frictional action (which can be attained from a selection of properly graded aggregate skeleton), rutting related to lateral displacement (plastic movement) can be induced along the wheel path in the pavement. Rutting from the loss of mastic phase or fine grains of aggregate in surface layer due to the abrasive action of steel-studded tires can also occur. This latter phenomenon, in particular, is heavily observed in the transportation jurisdictions where studded tires are still allowed, specifically in northern states in the United States, Canada, and northern Europe. Not only does rutting significantly affect travel performance, but numerous evidences also exist that it affects ride quality and road safety.

Safety implications: Many studies in the literature show that rutting plays an important role in crash occurrence. Rutted wheel paths can easily be filled with water from rain and snowmelt. On days with heavy rain, a road that has poor drainage design, precipitated water flow through the rutted strip on the road surface like a surface drain—which is, of course, an unfortunate and undesirable aspect for maintaining safety on roads. Rutting can significantly enhance the probability of the loss of vehicle control from hydroplaning. Splashed-water by a vehicle in front or a vehicle in a side-lane can suddenly cover windshields with muddy water, and thus it can impair a driver's vision for safe driving. Based on a study in Wisconsin in the United States, a Transportation Research Board article reports that the crash rate dramatically increases when the rut depth on wheel paths exceed approximately 7.5 mm (Start et al., 1998). Additionally, a deeper rutting channel on the wheel path can lead to plunging oscillation for the vehicle; this vehicle oscillation affects a driver's ability to control the vehicle or forces the driver to change lanes abruptly. The latter can cause a rear end, sideswipe, or roadway departure collision.

Potholes and Delamination

Potholes are localized distresses in the form of bowl-shaped holes of varying sizes—created by the loosening of asphalt film, mastic, and aggregates due to adhesive and cohesive failure in the road materials through water and traffic action. Therefore, potholes often

Figure 2 Potholes distress on a roadway. *Source: Photo used with permission of A. Hawthorn.*

form in areas that have poor drainage, high traffic volumes, or frequent braking especially for heavy vehicles. Also, potholes are one of the prominent distresses in the region where road pavements experience a relatively high amount of freeze-thaw cycles during the winter months. Basically, during the freeze-thaw cycle, expansion and contraction occur in pavement materials. Thus, these expansions and contractions induce stresses in pavement and nucleate micro cracking. With the traffic loading, moisture and water from the atmosphere, rain, and snow, the small-crack turns into bigger holes. Besides, from the thawing of ices, voids, or holes are created in the pavement structure. **Fig. 2** shows a series of pothole in a service lane. Delamination is the gradual removal of an area of asphalt surface due to poor bonding with the underlying paving layer. This type of distress reduces the serviceability and road safety of the pavement as they can create water ponding in the road, which ultimately affects driver's driving behavior.

Safety implications: Physical defects, such as potholes and delamination can influence the driver to change the driving lane abruptly or swerve around the pothole. These types of driving actions are associated with high collision rates, especially on multi-lane roads. However, just making a road pavement smoother without improving its friction and without improving roadside features can lead to higher speeds and higher crash rates as observed on two-lane rural roads in New York State. So, in order to maximize safety, smooth pavement should be strived for and at the same time speed should be controlled and enforced through other means than by having people slow down by navigating around potholes. And even if drivers try to navigate around potholes, they often miss one and the damage to the vehicles wheels, suspension and shock absorbers can have serious implications on their safety at a later time.

Cracking and Roughness

Various types of pavement cracking occur in the life of a road pavement. They include fatigue, thermal, moisture, and aging/stiffness-related cracking. The cyclic loading from vehicular traffic, pavement temperature, frequency, and magnitude of the change of air and pavement temperatures can contribute to fatigue-related cracking. Pavements in regions with frequent freeze and thaw cycles, and/or extremely cold climate experience relatively more thermally induced stresses (from repeated contraction and expansion in pavement materials); this leads to thermal-related cracking. When an asphalt pavement ages, it becomes stiffer and exhibit more brittle behavior. With the loading from vehicular traffic, a stiffened pavement exhibits age-related cracking. If these pavement cracks are not treated in a timely manner, as indicated above, they can lead to bigger holes "potholes" which can have severe consequences on traffic safety.

Additionally, pavement cracks combined with other factors including pavement surface properties, extent, and severity of pavement distresses contribute to pavement roughness ([Hall et al., 2009](#)). Pavement roughness is generally defined as an expression of irregularities in the pavement surface that adversely affect the ride quality and safety. Degradation of the pavement roughness has a significant impact on safety. Roughness is measured from the vertical movement of a vehicle traveling at a speed of 80 km/h and is defined as the ratio of accumulated suspension motion of a car to the distance traveled ([Sayers, 1995](#)). Roughness is expressed in meters/kilometers or inches/mile. It commonly ranges from a value of about 1–5 m/km on a paved highway.

Safety implications: Low roughness values normally indicate a smooth surface. According to the US Federal Highway Administration, high-speed pavements with roughness value greater than 2.7 m/km are classified to be in "poor" condition ([Guerre et al., 2012](#)).

Patching

Generally, pavement patching is conducted to repair local distresses temporarily. A thin layer from the faulty area of the pavement is removed and replaced with a new paving material. Patching contributes to address road safety and ride quality issues. In general, less preparation and care are taken to conduct a patching project. Thus, patching areas are often found as an elevated area from the true planar road surface.

Safety implications: Patching can influence drivers to change lanes suddenly and can lead to rear-end, sideswipe or run-of-road crashes.

Low Surface Friction

From a roadway perspective, pavement surface friction mainly depends on the surface texture of the pavement, surface temperature, and moisture availability on the road surface. The surface texture refers to the deviations of a pavement surface from a given true planar surface, and it varies with the physical characteristics and gradation of aggregates used in the road construction and design of paving mixture (Hall et al., 2009). The sizes, angularity, shape factor, and durability of the aggregates used in pavement construction will dominate the pavement surface texture. Typically, the surface friction decreases over the pavement life as aggregates become polished by traffic action. And, frictional resistance (skid resistance) between the tire of the vehicle and the pavement surface has a profound effect on road safety. Therefore, during highway geometric design, the pavement friction value for the given pavement type is needed to determine the design values of stopping sight distance, highway curve radius and length, and superelevation.

Safety implications: A higher pavement surface friction value would mean that the driver would have more control of their vehicle when the pavement is wet or has a film of water on it.

Road Safety Improvement Through Summer Road Maintenance

Numerous studies present that poor road conditions significantly influence traffic safety and travel performance. Therefore, transportation agencies across the world strive to improve road safety by conducting proper road maintenance through delivering various road programs. When road conditions are evaluated along with road safety in terms of the number of collisions and their level of severity, obtaining a complete picture of various engineering and functional properties including the pavement's physical conditions, materials and mix designs, geometric designs, and roadway safety features, is essential.

Highway safety can be improved through active and passive safety programs. An active safety program is delivered through preventive changes to roadway features (e.g., installing high friction surface courses, guard rail) to prevent or reduce the severity of accidents. Pavement maintenance programs can be delivered as an active safety strategy by reducing distresses or deterring the deterioration rate of pavement surface conditions with rutting, potholes, cracking, and roughness.

Rut Maintenance

Minor surface ruts or a small strip of the rut can be filled with asphalt patching materials, and deeper ruts can be covered by applying an overlay in the rutted lane. If the surface asphalt layer is unstable, recycling and repaving can be performed to get rid of rutting. In the case of ruts related to subgrade inconsistencies, reconstruction is the best option.

Pothole Maintenance

Potholes can be repaired by asphalt patching work or by rebuilding a road section that has a relatively large number of potholes. Patching is a very common method used to cover up the potholes. Within patching methods, "throw-and-go" is the most widely used patching method (Simita et al., 2016). In this method, asphalt materials are placed into the pothole and then they are compacted with the maintenance vehicle tires. This is often done hastily and thus it leaves an elevated crown above the road surface plane. A semi-permanent pothole repair method can also be performed, and the performance of this method is better than the "throw-and-go" method. This method requires that water, disintegrated debris and aggregates are removed as much as possible before placing the asphalt mixture and compacting it with a proper compaction system. Edges of the patching area are leveled to obtain a smooth continuous pavement surface. Spray injection is another efficient pothole repair method that can be done to cover potholes. This process combines hot asphalt emulsion and crushed aggregate and uses forced air. Cleaning of debris and spraying tack coats are performed to further enhance the performance of this pothole repair method. If a road section is full of deep potholes, an overlay or reconstruction can be a suitable option, dependent on the severity of potholes.

To identify subsurface delamination effectively, non-destructive test methods, such as Ground Penetrating Radar or strain gages can be used. Delaminated areas can be treated by milling off the surface layer, replacing the wearing course, or placing a thin asphalt overlay.

Pavement Crack Management

To measure the extent of cracks, such as fatigue cracks or block cracking, the linear distance of the affected wheel path or square meters of the pavement area is considered. The affected zone can be classified according to the level of severity that can help rank the roads need in maintenance for allocating scarce maintenance dollars. A full depth patch or spray patching can be performed for temporary repair for fatigue cracking areas. A thin wearing course can be constructed to repair a low severity block cracking. For more severe situations, overlay with or without recycling can be performed. For base problems, reclamation and reconstruction of the pavement can be done. For longitudinal and traverse cracks, the number and length of cracks at each severity level are measured. Crack sealing can be performed for low severity cracks and an overlay can be placed for high severity cracks.

Figure 3 High friction surface treatment for enhancing pavement friction—treated (A) and untreated (B). *Source: Photo used with permission of The Transtec Group, Inc.*

Surface Friction Management

Maintaining safe friction on pavement surfaces is indispensable for road safety. Various high-speed and low-speed or stationary equipment including Locked-wheel skid trailer, Mu-meter, Fixed slip grip-tester, British pendulum tester, Sand patch system can be used to measure friction on pavements. Highway agencies aim to maintain an appropriate level of surface friction for all road sections within the network, based on each section's friction demand which depends on traffic volume levels, highway class, climatic zone, and crash history. The road sections that have friction values less than the friction demand value can undergo more rigorous testing in terms of micro and macro textures of the pavement surface and crash pattern. This process can help design immediate intervention with appropriate surface maintenance project to restore friction demand value. **Fig. 3** shows a treated and untreated pavement section, where an epoxy-based aluminum oxide additive is used to improve friction on the road surface.

The US National Cooperative Highway Program Report No. 108 indicates that aggregates' mineralogy, hardness, shape, angularity, and polish and abrasive resistance influence on pavement friction. Therefore, during pavement surface maintenance or reconstruction of pavement, a comprehensive material and mixture testing system can help identify the right recipe that can generate an appropriate combination of micro and macro textures in the pavement surface. The literature shows that using an appropriate surface friction course opposed to conventional asphalt mixtures can lead to millions of dollars in savings from reductions of crash numbers. **Table 1** summarizes the major roadway distresses, their road safety threats, and treatment options for improving road safety.

Winter Road Surface Conditions and Road Safety

Winter Road Surface Conditions

Winter weather can cause pavement surfaces to be contaminated with snow and ice, resulting in reduced surface friction. Pavement surface contaminants are the eventualities or products of snow after some external forces and actions. For example, compacted snow after plowing by truck or manual power, slushy snow due to positive thermal changes and traffic actions, and bonded ice due to the

Table 1 Pavement distress, road safety risks and treatment options

<i>Pavement distress</i>	<i>Road safety risks</i>	<i>Treatment options</i>
Ruts	Moderate to high	Asphalt patching Overlay Reconstruction
Potholes	High	Asphalt patching—throw and go, semi-permanent method Spray injection Reconstruction
Longitudinal and traverse cracks	Low	Crack sealing—rout and seal Seal coat—chip seal, slurry seal
Low friction pavement (Polished pavement surface)	High	Thin overlay High friction surface course Open-graded asphalt course

temperature falling below the freezing point are all types of pavement contaminants. Winter pavement surface conditions could vary significantly by contaminant type, coverage, and depth; however, in practice, they are commonly classified into four types, namely, surface with loose snow, packed snow-covered surface (leftover from a plowing operation), icy pavement surface, and wet pavement. These contaminants reduce the serviceability of a road, increasing travel times, or pose a threat to traffic safety.

Loose Snow-Covered Surface

Road surfaces become contaminated with newly fallen snow. The type of snow can vary from very loose to very packed, and thickness can vary from very thin to very thick amounts. A bond can start to form under the top layer of the snow when the pavement temperature falls below the freezing point. Road safety characteristic, that is, the surface friction of this type of pavement largely depends on the amount and physical properties of the snow (e.g., crust/packed snow vs. loose snow) rather than whether the snow is bonded with the pavement surface underneath or not.

Packed Snow-Covered Surface

This type of road surface can be observed when snow is present either in compacted form or in patches of snow after the snow has been plowed either by truck or manual power—which in North America is used primarily in small parking areas or walkways. If the initial snow is wet or the temperature is above the freezing point, a bond does not form and the snow can be mostly cleared by only plowing, leaving patches of snow; however, in the case of dry snow, plowing operation can leave the pavement with compacted snow. Thus, the friction of this type of pavement could become quite low (e.g., 0.20–0.50), either for initial snow type (e.g., dry snow vs. wet snow) and/or plowing method (manual plow vs. truck plow). Minor highways in some northern US states, and all roads in, for example, northern Sweden and all of Finland—including city streets and freeways—are always left “white” during all of the winters. They are plowed to be travelable but never salted and typically not sanded either except for in steep hills and at stop signs. Also, sidewalks are sanded but not salted.

Icy Road Surface

The pavement can be contaminated with ice when the temperature tumbles below the freezing point and no appropriate snow-melting chemicals (e.g., salt) have been applied to control the snow contamination. Icy pavements can also be caused by freezing rain, which happens when the ground and roadway temperatures are below the freezing point but the atmosphere above the roadway is warm. In addition to the regular ice, another type of ice is also observed, referred to as “black ice” in Canada or in northern states. This is a special type of ice that is formed when a very thin film of water on the pavement surface is frozen due to freezing temperature. “Black ice” is less visible than regular ice and has a much smoother surface. It can easily be overlooked and thus cause a higher risk of traffic accidents than a snow-covered road. Icy road surfaces pose significant threats to both vehicle and pedestrian safety during the winter season. The friction coefficient for an untreated road covered by ice may be as low as 0.1 (Hossain et al., 2015).

Wet Pavement

If the pavement is clear of contaminant types mentioned earlier, but is damp with a thin film of water from snow melted solution or winter precipitation, it is considered to be a wet pavement. Note that, in the cases where the puddles of water were present, pavement friction can certainly fall down below a safe friction value (approximately 0.40) and pose a significant threat to traffic safety. Over 12% of the total number of accidents that occurred between 2000 and 2009 in the United States occurred on wet pavements with reduced pavement friction (McGovern et al., 2011). **Table 2** summarizes the various winter road conditions, their threat levels to road safety, and treatment options to mitigate road safety issue.

Winter Road Safety

The accumulation of snow and ice contaminants on a pavement affects the mobility and safety of pedestrians and vehicular traffic. For example, every year there are thousands of pedestrians in Sweden who are injured because of slippery pavements and roadways and studies in that country shows that foot slippage caused 43% of all falls and 16% of all accidents at work, in the home and during leisure activities in the Nordic countries (Lund, 1984). Two-thirds of these slips occurred on sidewalks or other surfaces covered by ice and snow. Studies in other countries have also shown that surfaces covered with snow and ice increase a pedestrian’s risk of slipping and falling by reducing the average level of traction (friction) of the pavement surface. Fundamentally, slips and falls are caused by a loss of traction or friction between the pedestrian’s shoes and the surface being walked on. Pedestrian injuries on slippery surfaces are more severe than those on non-slippery surfaces. Therefore, maintaining safe traction or friction on these surfaces is critical to the safety of pedestrian and vehicular traffic during the winter months. To improve the surface conditions (i.e., the friction level), both public and private organizations put large efforts and resources into making sure the public is safe under winter weather conditions. However, in contrast to highways, parking lots and sidewalks are commonly maintained by small contractors and/or individual property owners, who may have varying or loose guidelines to follow for controlling snow and ice on these areas. This

Table 2 Winter road conditions, road safety risks, and treatment options

<i>Winter road conditions and weather events</i>	<i>Road safety risks</i>	<i>Treatment options</i>
Heavy snowfall forecast	Medium to high	Anti-icing—dry, pre-wet salt, or liquid salt application Do nothing and wait for forecast to be true
Road surface covered with loose snow	Low to high	Plowing only Deicing with dry or pre-wetted salt Plowing and deicing Abrasive use
Packed snow-covered road surface	High	Deicing with dry or pre-wetted salt Abrasive use
Icy pavement surface	High	Deicing with pre-wet solid salt or direct liquid Abrasive use
Wet pavement	Medium to high	Abrasive use Anti-icing, if temperature continues to drop

lack of uniform standards and guidelines is considered as one of the main factors contributing to significant legal challenges of slip-and-fall cases and over application of salt in fear of the former. From a sustainability perspective, a majority of the contractors applies excess salt to avoid slips and falls, in order to avoid litigations and increases in insurance premiums.

Reduced pavement friction due to snow and ice contamination contributes to increased collision risk for vehicular traffic. Therefore, vehicular traffic is significantly more likely to be involved in accidents in the winter than in the summer for a given distance of travel. With respect to fatal crashes, there is a reduction in the number of fatalities during the winter months in northern states of the United States and in the Nordic Countries. For example, in Sweden, the number of fatalities from traffic accidents for January through April is roughly half of that for May through August. And, in Maine, February has had the fewest fatalities of any month for each year during at least the last 10 years in spite of February typically is the month with the most snowfall. The primary cause that the snowiest months have the fewest fatalities is that people avoid traveling in winter weather. But, heavy snowfall and white roads also make people drive slower so that when they have accidents; they are less likely to be fatal. However, black ice is often missed by drivers and as long as we do not have good information systems informing drivers—or their cars—of that situation, black ice can and does increase fatality rates. Winter snow and ice-related traffic crash costs including both personal injury and property damages are in the range of billions of dollars each year globally. Various factors influence road safety in the winter season. The major factors affecting winter road safety are snow, ice, rain, and visibility from a weather perspective; vehicle speed, traffic volume, and vehicle safety features from a traffic perspective; and operational strategies, treatment types, degree, and efforts from winter road operation perspective. Suitable winter road maintenance can improve road safety in the winter months but studies in Maine indicate that injury rates are only marginally improved by improved winter maintenance. The big gain from improved winter maintenance is keeping travel times close to normal summertime values saving people large amounts of time. Various winter maintenance methods are employed which are based on the existing surface contaminants, expected snow event characteristics, traffic level, and level of service (LOS) requirements for the road.

Winter Road Maintenance Strategies, Materials, Guidelines for Improving Road Safety

Winter Road Maintenance Strategies

Transportation agencies that experience any amount of snowfall during winter months have adapted various methods of snow and ice control. These methods can sometimes vary according to winter behavior for that specific geographic area, and may include methods, such as plowing, salting, sanding, etc. Winter maintenance methods can be classified into three distinct categories: chemical, mechanical, and thermal categories. Applying a snow control chemical (e.g., sodium chloride) as a freezing-point depressant on pavement or integrating the freezing-point depressant into the pavement is an example of a chemical method. Methods such as plowing, scraping, or using high-velocity air to blow snow are all classified as mechanical. Finally, thermal methods include those that control or prevent the formation of snow through the application of heat, either from above or below the pavement surface. Recent technological and logistical developments have allowed a higher level of diversification in snow and ice control. Many different types of winter operations are currently in use, including deicing (e.g., post-salting only, plowing, and salting after), anti-icing (e.g., pre-salting only, pre-salting, and plowing after), and application of pre-wetted solid salts, liquid salts, or even combinations of these methods (Hossain et al., 2018). The following provides an overview of common snow and ice control methods.

Plowing

Plowing is the most basic form of snow and ice control that exists today. The exclusive use of plowing is often the most economical way to treat snow at some establishments, especially those with low LOS requirements. Despite this, a plowing only

method can still be effective even when a higher LOS is needed, if snow does not bond to the pavement, or if a white road is an accepted outcome as in most regions of the Nordic countries. For places where the exclusive use of plowing is not sufficient, it can be made more effective if it is conducted in conjunction with anti-icing. Indeed, a large number of studies indicate that crash rates decrease significantly after plowing.

Deicing

Deicing is a method of snow and ice control in which chemical agents are applied to melt the snow and ice already accumulated on a pavement surface. Chemical agents work by lowering the freezing point of water or by breaking the previously formed bond between snow and pavement. The most common type of salt for this application is rock salt; and, depending on the types and amounts of salts being used, these deicing methods can be effective at temperatures ranging from -7°C to -12°C .

Deicing treatment can also be conducted with other alternative materials, some of which contain less or no chlorides and thus have lower environmental effects. Salt can be pre-wetted using brine or other liquids for improved performance. Pre-wetting has been shown to be an effective method to provide a higher LOS for the following two reasons. First, wet salt can better adhere to the pavement surface, resulting in less scattering, and less material usage. Second, salt requires moisture to activate the deicing process.

The deicing operation has several unavoidable issues. First, the most common deicing chemical used is sodium chloride, and its application has the potential to cause substantial problems including contamination of drinking water and sub-soil layers and corrosion of concrete pavement and motor vehicles. Second, because of poor roadway conditions, both prior to and during maintenance, the potential for accidents may be increased when deicing operations are conducted. Additionally, it is important to note that deicing may also consume large amounts of snow control materials and labor to achieve a desired LOS.

Anti-Icing

Anti-icing is a strategy, which applies snow and ice control materials before or immediately after a snow event starts. The objective of anti-icing is to prevent the bonding of snow and ice to a pavement surface. If an anti-icing treatment is conducted at an appropriate time of the snow event, and not during severe storm conditions or on an extremely cold pavement surface, that is, colder than -8°C (23°F), it can be very effective. The anti-icing operations can contribute to cost savings for both highway agencies and motorists by reducing the use of materials and by reducing the number of accidents, respectively. In addition to its benefits against regular winter weather, anti-icing is particularly effective in dealing with heavy frosts.

In applying an anti-icing strategy, both solid and liquid chemicals can be used. Solid chemicals specifically have been in use for many years in anti-icing operations. If dry solid anti-icing agents are applied, the moisture in the air must be sufficient, as moisture reduces the ability of an anti-icing agent to be blown off the road by causing it to stick to the pavement. In addition to this, moisture has also been shown to improve the performance of applied chemicals. For roads, solid salt with water or another liquid chemical is recommended in order to minimize the bounce and scatter tendencies of salts and reduce the loss of particles from wind-blow caused by vehicular traffic.

Abrasive Application

The main objective of using abrasives is to provide improved traction on ice-covered roadways, especially when it is too cold for other chemicals to work effectively. Transportation and environmental agencies also prefer using abrasives when roads are too close to a water body, such as a lake, river, and pond, to reduce the impact of deicing salts in water quality. Abrasives such as sand and sand-salt mix are commonly used to provide improved traction on ice-covered roadways. Several kinds of abrasives can be used for snow and ice control, including natural sands, finely crushed rocks or gravels, bottom ashes, slags, ore tailings, and cinders. The application rate for abrasives varies among the different winter maintenance agencies due to the diverse weather conditions. It is important to note, however, that since most of the abrasives used are inert substances (e.g., sand), they will not help melt snow and ice. Moreover, abrasives can be expensive when the total costs of handling, cleaning, drainage, and environmental costs are considered. Also, pure sand tends to be swept away by trucks traveling at high speeds, so the treatment may lose most of its effect already after 10–20 trucks have passed by whereas salt sticks to the surface and the effect last much longer.

Combined Maintenance Strategies

Because winter weather events in different areas present a variety of weather and pavement conditions, a combination of strategies is almost always used (Blackburn et al., 2004). Different LOS requirements, scope of services, and maintenance agency's ability to provide various combinations of maintenance methods can influence to design combined maintenance strategies, such as using abrasive and chemical mixes, using mechanical and anti-icing methods at the same time, or applying mechanical and abrasives.

Table 3 Properties of some common snow and ice control materials

Material	Chemical composition	Forms used in snow and ice control operations	Eutectic temp and Eutectic conc. °C (°F)
Sodium chloride	NaCl	Primarily solid, but increasing use of liquid	–21 (–5.8) @23.3%
Calcium chloride	CaCl ₂	Mostly liquid brine, some solid flake	–51 (–60) @29.8%
Magnesium chloride	MgCl ₂	Mostly liquid brine, some solid flake	–33 (–28) @21.6%
Calcium magnesium acetate	CaMgAc	Mostly liquid with some solid	–27.5 (–17.5) @32.5%
Potassium acetate	KAc	Liquid only	–60 (–76) @49%
Agricultural by-products	NA	Liquid only	Usually blended with chloride-based products
Other organic materials	NA	Liquid only	Varies with product

Overview of Snow and Ice Control Materials

Snow and ice control materials include various chemical products as well as abrasives. Deicing materials can generally be classified into two types, namely chloride-based and nonchloride-based. The most commonly used chloride-based materials include sodium chloride (NaCl), calcium chloride (CaCl₂), and magnesium chloride (MgCl₂). These materials are generally produced from the mining of surface or underground deposits, extracting and fractionating brine from wells, industrial by-products, or through solarizing saltwater.

Nonchloride-based products, also called organic products, are mostly manufactured. Some are wholly synthesized (e.g., CMA and KA) while others are refined from agricultural sources (e.g., by-products from grain processing, brewing, winemaking, and similar sources). These materials are not as popular as chloride-based products, but are used as either stand-alone liquids, blended with inorganic liquids, or as stockpile treatments. In general, due to their high costs, they tend to be used for special situations (e.g., for low-corrosion applications, such as bridge decks). Most of these products are proprietary with little information about their actual manufacturing and refining process. These products are usually used in conjunction with chloride-based products, though stand-alone products have also been marketed. Many of these products have been claimed to have the benefits of being less corrosive and more effective in snow melting. Table 3 presents the chemical properties of common snow and ice control chemicals used.

Winter Road Maintenance Guidelines

This section gives an overview of winter road maintenance guidelines that can help the maintenance industry responsible for snow and ice control of highways, parking lots, and sidewalks to optimize maintenance operations and minimize salt usage.

Determining the Level of Service Need

Any maintenance program for a transportation facility starts with establishing the desired LOS that should be delivered during the winter event or the winter season. The desired LOS must be realistic and cost-effective due to the random nature of winter events. As a result, it is preferable that each LOS standard includes a probability quantifier. Some highway agencies designate that all Class I highways (high priority) must reach bare pavement within 8 h for 90% of the events over a season, that is, the LOS requirement for Class I highway is 8 h. Standards of this type also make sense from the users' point of view, as it would understandably be too cost prohibitive to maintain a facility in a bare pavement condition at all times and under all types of events. Another consideration in setting LOS targets is the need to strike a balance between costs and benefits. An ideal LOS policy for a parking lot should take into account the types of snow events that are to be expected in the area where the site is located as well as the service demand of the parking lot/establishment type (e.g., shopping plaza, restaurants, emergency buildings, etc.). Also, the public could reasonably expected to be able to travel at high speed at all times on Class I highways but should not have the same expectation for a residential, urban street. To salt urban streets and keep them with bare pavement in the winter should probably not be a goal in northern states. Rather, if safety rather than automobile mobility is a primary objective, it should be a priority always to keep sidewalks and crosswalks bare and they should be treated before the automobile travel lanes are plowed or salted. That should be in the municipal plan as it typically is in the Nordic countries.

Determining Snow and Ice Control Treatment

In responding to any upcoming weather events, maintenance operators must choose the right winter maintenance treatment, such as anti-icing or deicing and the application rate for each treatment. If an anti-icing operation is to be implemented, solid or liquid salt should be selected on the basis of LOS need and the expected event conditions. The recommended application rate should then be applied before the event begins.

For deicing operations, a number of weather conditions should be determined at the time of treatment. First, the average representative pavement surface temperature should be either measured or estimated on the basis of air temperature and site

conditions. Second, the type of snow and the total amount of the snow (depth) that is expected to accumulate during the event should be determined. The snow accumulation should include snow already present on the ground in addition to the forecasted precipitation. Finally, the desired LOS should be determined in terms of bare pavement regain time, based on the LOS requirements of the facility.

The Snow and Ice Control Guidelines for Materials and Methods developed by National Cooperative Highway Research can be consulted for highway salt application rates, whereas *Deicing Performance of Road Salt: Modeling and Applications*—an article published by the Transportation Research Board can be considered for determining optimal application rate for parking lots, sidewalks, and low volume roads (Blackburn et al., 2004; Hossain et al., 2014).

Introduction

At-grade intersections may cause major bottlenecks in any roadway network system. Poorly designed intersection not only creates crashes but also leads to vehicular emissions and congestions. Crashes at intersections differ depending on the intersections' design and type. The design of an intersection should provide a safe and convenient environment for vehicles, bicycles, and pedestrians traveling through the intersection. Moreover, the design should aim to reduce the severity of potential conflicts between the users. There are two main types of intersections: grade-separated and at-grade intersections. In the case of at-grade intersections, two or more roadways cross at the same elevation. A roundabout is one type of at-grade intersection. For the grade-separated intersections, typically two roadways cross each other at different levels, but unless both roads are motorways (freeways), there are usually at-grade intersections between the minor road and ramps from the major road and those intersections can be yield-controlled, stop-controlled, signalized, or roundabouts.

Roundabouts rely on a physical barrier in the form of a central island to manage traffic compared to using only a regulatory sign or a traffic signal. Intercepting roads feed traffic into a one-way circulatory roadway that surrounds the central island. In this case, traffic is forced to move in one direction in the circulatory roadway, which typically is safer and more efficient than other types of intersections where a driver can run a stop sign or a traffic signal. All movements that drivers make when entering, while inside, and when leaving the roundabout are right turns, which is safer, and cause less delay than left turns. To make a U-turn, drivers have to circle all the way around the central island and exit the roundabout on the same street they entered it from.

As a treatment for the traditional intersection, roundabouts offer a safe, efficient, and economical solution to traffic signals in most situations if adequately designed (Elvik, 2003; Hydén and Várhelyi, 2000). Often, they are also less expensive to construct and maintain than signalized intersections. The maintenance cost is mainly related to standard roadway maintenance in addition to lighting and landscaping. The central island also provides space for landscaping, which is more esthetically appealing than a traditional intersection design. However, traditional modern roundabouts often require more right-of-way at the intersection itself than other types of control, which can increase the construction cost substantially if not available at an existing intersection. On the other hand, roundabouts keep traffic moving all the time, so sections between the intersections can be made narrower, saving right-of-way costs and construction costs, especially where several roundabouts are built in series along a so-called roundabout corridor.

After having been implemented and proven successful at numerous locations across the world, roundabouts have been incorporated as a standard design in many countries as a solution to congestion, high vehicle and pedestrian crash rates/counts, and a low-maintenance cost solution to the traditional signalized intersections. Today, after many years since the development phase, there are different types of roundabouts used around the world. Some types are already in frequent use in many countries; some of them are recent and used in specific countries, and others are still in the development phase. Therefore, there are still different points of view regarding the ideal roundabout from the perspective of safety. In this article, the description, advantages, and disadvantages of the most common types of roundabouts will be discussed.

Modern Roundabouts

Roundabouts have existed since before there were any automobiles, and they were typically built to act as landmarks. The first roundabout built with an intent to make automobile traffic flow smoother and safer is probably Sollershoth Circus in Letchworth Garden City, the United Kingdom, which was built in 1909. The inscribed circle diameter is 33 m (108 ft). When first built, there was no centerpiece beyond a grassy circular island, so this was not a case of locating a civic ornament, but just traffic engineering. Today, lighting and bushes have been added to the central island. However, with no one-way rule and no traffic priority, it was not exactly a modern roundabout at first but functioned well since traffic volumes were low, and the United Kingdom had a national speed limit of 20 mph (32 km/h) at the time.

The modern roundabouts are said to have been invented in the United Kingdom in order to eliminate the problems associated with larger traffic circles as traffic volumes increased and traffic circles experienced congestion because of traffic in the circle yielding to entering traffic and a high number of crashes because of high speeds. In the United Kingdom, they standardized yield at entry in November 1966. Sweden followed with a universal yield at entry in September 1967, and several other countries changed priority around that time as well. But in the United States, different states had conflicting rules, and there are still circular intersections in the United States where entering traffic has priority. In the United States, “standard” roundabouts are since the early 1990s called modern roundabouts to avoid confusion with the larger traffic circles and rotaries.

Modern roundabouts, like older traffic circles, are designed as one-way circulating roadways with channelized approaches and yield control on all entries. The main difference is that modern roundabouts have geometric curvature that creates a low-speed environment. Modern roundabouts can be classified under two categories: one-lane and multilane roundabouts. For single-lane roundabouts, the design is fairly easy, but to create a low-speed environment for multilane roundabouts has proven to be a challenge. Over 90% of roundabouts in France, Germany, the Netherlands, and Scandinavia are single-lane roundabouts and, in most of these countries, there are now more roundabouts than signalized intersections. In the United Kingdom, they often widen single-lane approaches to accommodate parallel vehicles in the roundabout itself, and allow “double” circulating lanes without any striping.

This is not the case for the rest of Europe or most of the United States where striping is used when allowing parallel vehicles in the circulating area. In some countries, concentric striping is still used, meaning a driver will have to change from the inside to the outside lane before exiting a roundabout from the left lane. Nowadays, typically exit striping is used instead. In this case, a driver picks a lane at entry and keeps that lane until they exit, except for if they want to make a U-turn, then a lane change is needed. This exit striping gives the modern roundabout somewhat similar characteristics to the turbo roundabout discussed later, except that many drivers do not stay within their lanes if they are separated only with striping.

As drivers enter a roundabout, they should slow down to get ready for crosswalks at the approach and then for the “intersection” itself. They should be able to see circulating traffic before they reach the yield line. When possible, vehicles merge with traffic inside the roundabout without stopping if a sufficient gap is available within the circulating traffic. Once in the roundabout, vehicles travel with the circulating traffic around the central island.

Operational speeds within a roundabout should be no more than 25 km/h (15 mph) on average, and the 90-percentile should not exceed 32 km/h (20 mph). However, many multilane so-called modern roundabouts have top speeds around 50 km/h (30 mph). The low speed should be achieved without signage indicating the speed limit within the roundabout, but an advisory speed limit sign recommending 25 km/h (15 mph) can be useful in areas where roundabouts are unusual. The geometric curvatures should ensure safe circulatory travel speeds. If bicycles share travel lanes in a roundabout, it is extra important to ensure that all cars travel at low speeds and speeds across crosswalks should never exceed 30 km/h (18 mph). When a vehicle approaches the required exit, in most jurisdictions, the drivers use their right-turn signal then turn right in order to exit the roundabout.

Modern roundabouts in high-speed environments in Scandinavia were often offset to the left already in the 1980s as seen in **Fig. 1**. The sharp deflection at entry ensures low entry speeds, but a potential safety issue is that the lack of deflection at the exit gives too high speed across crosswalks at exits. In the United States, such offsets have been introduced in the last decade, but the standard design in most countries is to have approaches centered toward the middle of the center island. Still, there are variants in the design of modern roundabouts.

Speeds within the roundabout are typically slower compared to a traditional signalized intersection, which gives drivers more time to handle potential conflicts. Moreover, in the case of a crash, the severity of damages and injuries is much lower than in high-

Figure 1 Typical Scandinavian roundabout.

speed crashes. Furthermore, since vehicles travel in the same direction through a roundabout, some of the most serious crashes that occur at signalized intersections (right-angle, left-turn, and head-on) are virtually eliminated.

Well-designed modern roundabouts have a good safety record. A study showed that the construction of roundabouts resulted in a reduction in the number of injury crashes in Australia (45%–87%), France (57%–78%), the United Kingdom (25%–39%), and the United States (51%) (Robinson et al., 2000). Another study indicated that converting intersection to roundabouts resulted in a 30%–50% reduction in the number of injury crashes and a 50%–70% in fatal crashes (Elvik, 2003). A similar study showed an 80% reduction for all injury crashes and about 90% in the numbers of fatal and incapacitating injury crashes (Persaud et al., 2001). In general, roundabouts are proven to reduce the high percentage of crashes where people are seriously injured or killed.

Most of the recorded crashes at roundabouts are glancing blows at low angles of impact, reducing crash severity, and an occupant of a car or truck is seldom seriously injured at speeds below 50 km/h (30 mph). However, a typical pedestrian has a 20% chance of dying if hit at 50 km/h (30 mph), and new US data show that a 70-year old pedestrian has a 37% chance of dying if hit at that speed by the typical vehicle, and an even higher risk of dying if hit by a pickup truck or SUV where the pedestrians' center of gravity is below the hood of the vehicle. Furthermore, bicyclists and motorcyclists are prone to get injured if hit at moderate speeds.

A summary that was made on May 12, 2019, shows there so far (from 1990 to 2019) have been 81 fatal crashes at modern roundabouts in the United States, killing 89 people. One pedestrian and two bicyclists have been killed, but at least 30 motorcyclists are victims. A number of the victims are shown as unknown type, but motorcycles make up over a third of all fatalities. Motorcyclists can get killed at low speeds, and motorcyclists also sometimes enter roundabouts at speeds way above the intended speed, losing control. In other words, roundabouts typically improve safety performance compared to other types of control, but in order to be safe, it is essential to ensure that everybody travels slowly. Because of their low-operating speeds, single-lane roundabouts are used as a traffic-calming device in many countries.

The conflict points between vehicles for a traditional four-leg intersection of two-lane roads are shown in Fig. 2. Traditional intersections have 32 vehicle/vehicle conflict points, including 8 merging points, 8 diverging points, and 16 crossing points. Modern roundabouts only have eight total conflict points, including four merging points and four diverging points. The crossing movement is eliminated as a potential conflict due to the central island. This is a 75% reduction from traditional four-way intersections. In the case of a three-leg intersection, the number of conflict points decreased from nine to six in the case of a roundabout, which is a 33% reduction. The reduction in the number of conflict points is an indication of few possibilities for crashes. This is one of the main reasons that a one-lane roundabout could offer safety conditions than a stop-controlled intersection under the same conditions. Furthermore, having few automobile conflict points gives the driver more time to look for pedestrians, especially if the driver is also slowed down to a lower speed than at a traditional intersection.

In the case of roundabouts with two circulating lanes, there are more conflict points compared to one-lane roundabouts, especially if lane changing occurs inside the roundabout, and dual entry and exit lanes may also cause confusion. In this case, there are 24 vehicle/vehicle conflict points: 8 crossing points, 8 diverging points, and 8 merging points. By replacing a traditional intersection by a two-lane roundabout, the number of conflict points is reduced from 46 to 24, 48% (Fig. 2). This may be a reason why safety appears to be better in one-lane roundabouts compared to two-lane ones. However, a more important reason may be that parallel lanes allow drivers to go much faster, especially if a driver enters in the right-hand lane, cuts into the left lane at the central island, and then again exits in the right lane. That is possible if the lanes are separated by only striping, and there is no vehicle in the other lane.

Flower Roundabout

In spite of the good performance levels of modern roundabouts, especially multilane ones have shown safety problems mostly associated with the behavior of the drivers at the entries, inside the roundabout, and at the exits, such as disregarding lane markings, improper lane changing, and speeding. Such behaviors can cause safety problems and increase the risk of crashes. Researchers have resolved the problems of the modern two-lane roundabouts by adopting new types of roundabouts. One such type is the flower roundabout (Fig. 3), which only has one circulating lane (Tollazzi et al., 2011). This is more or less the only design used in Denmark when traffic volumes require more than one lane.

This type of roundabouts can have two entry and exit lanes outside the roundabout, but it has only one circulating lane. There is an additional right-turn lane that directs right-turning vehicles to turn right separate from the circulating traffic. The capacity is lower than for a double-lane roundabout unless a high percentage of traffic turns right. A related design that increases the capacity is to put separate right-turn slip lanes on a roundabout with two circulating lanes. The safety benefit of that is questionable, especially if there are high pedestrian volumes.

An advantage of the flower design is the possibility of implementation on any existing roundabout. If the before design was a single-lane roundabout, and it has long delays, adding slip lanes can help. If the before design had two circulating lanes, the paved circulatory area would have to be narrowed, and the outer lane is changed to a right-turn lane only. These modifications will reduce capacity but will increase safety.

In the case of a roundabout with one circulating lane, the central island and intercepting roads remain in the same positions, and a right-turn lane is created by adding a new lane or separating an existing outside lane, from the inside lane by a splitter island. In this case, the inside circulating lane is used by vehicles desiring to go straight, turn left, or make a U-turn. If a vehicle incorrectly stays in the inside lane when entering the roundabout, it can still turn right at the first exit as long as the slip lane has its own exit lane. This

Figure 2 Vehicle/vehicle conflict points for different types of intersections versus modern roundabouts.

Figure 3 Vehicle/vehicle conflict points for the flower roundabout for one- and two-lane roads.

should not be allowed if the design follows the left graph of [Fig. 3](#) because drivers in the slip lane look for traffic already in the roundabout and do not plan to yield to right-turning traffic entering from the lane that was parallel to them on the approach, resulting in sideswipe crashes at the merge area.

When separating the right-turning movement from the other movements of what used to be a roundabout with two circulating lanes, the two-lane roundabout becomes a one-lane roundabout. All crossing conflicts and weaving conflicts are eliminated. Therefore, there are only eight vehicle/vehicle conflict points: four diverging points and four merging points similar to a traditional one-lane roundabout. However, the diverging conflict points concerning the right-turning movement and the merging points with the flow from the roundabout result in an additional four diverging and four merging conflict points that are introduced before and after the roundabout. The total number of conflict points for this case is 16, which is still a better design compared to the traditional roundabout with 24 conflict points.

Turbo Roundabout

One of the new types of roundabouts adopted recently in many countries is the turbo roundabout. In 1997, this type of roundabout was developed in the Netherlands in order to solve the weaving problems of the two-lane roundabout ([Fortuijn and Harte, 1997](#); [Fortuijn, 2009a, 2009b](#)). The concept is based on physically separating the vehicles before entering the roundabout while circulating within the roundabout, and while exiting from the roundabout. The separation of the traffic lanes disturbed only the entry point to the inner circulating lane. The separation is achieved by the installation of raised splitters (delineators) to restrict lane changing within the roundabout and eliminate the weaving conflict points.

These geometric features of the turbo roundabouts force the drivers to select the proper lane before approaching the roundabout. They also prevent any lane changing at the entry, exit, or within the circulating lanes. These restrictions lower the number of potential conflict points during the roundabout crossing path, lower driving speed near and through the roundabout because of the raised lane dividers, prevent weaving maneuvers, and lower the risk for sideswipe crashes. All these factors cause the safety level to increase significantly.

In the case of a traditional two-lane roundabout, drivers can ignore lane markings, drive in an almost straight path, and sustain their approach speed. A turbo roundabout can increase the safety level of multilane roundabouts by eliminating some of these problems. The raised lane dividers force drivers to remain in the correct lane and to follow paths with smaller radius at reduced speeds. These restrictions result in a lower number of conflict points. An intersection between a major road with two-lane entries and exits and a minor road with two-lane entries and one-lane exits on the minor road will result in 14 vehicle/vehicle conflict points: 4 crossing points, 6 merging points, and 4 diverging points ([Fig. 4](#)) compared to 24 conflict points for a two-lane roundabout. Although turbo roundabouts lead to few traffic conflicts, the traffic conflicts that do occur are more severe ([Vasconcelos et al., 2014](#)).

One negative feature of the turbo roundabout is that a driver failing to yield when entering in the inner lane can be hit on the left side of their car almost perpendicularly, or they may hit the right-hand side of the circulating vehicle. However, since the entry

Figure 4 Vehicle/vehicle conflict points for the turbo roundabout.

geometry is very tight with a curvature guaranteeing low speed, there should be minimal risk of injury as long as one of the vehicles is not a motorcyclist or bicyclist. In the Netherlands, they, therefore, avoid this design if bicycles do not have their own separate lanes.

Pedestrian Safety

Pedestrian safety at roundabouts is considered high. The reduced speeds of the vehicles at roundabouts provide better crossing opportunities for pedestrians. In addition, the availability of a splitter island helps to provide a refuge area for pedestrians in order to focus on and cross one side of the road at a time instead of crossing the whole approach as in the case of un-signalized intersections. In addition, pedestrians can cross immediately in countries where pedestrians have the right-of-way in crosswalks, or as soon as a proper gap is available in countries where drivers have or take priority. Compared to waiting at a signalized intersection, this reduces the delay for the pedestrians. However, it also increases the delay for drivers, especially if the crosswalks at the roundabouts are signalized. Furthermore, the location of the conflicts between the vehicles and pedestrians occurs generally one car-length before the roundabout, which means the pedestrian does not have to walk in front of a driver stopped at the yield line, looking for traffic from their left. This results in few places for pedestrians to check for conflicting vehicles at the entry, whereas crosswalks at the exit are more similar to those at conventional intersections, but with traffic from only one direction and at a lower speed.

In a good design, a mid-block crosswalk is added to reduce the impact of pedestrian traffic on the functionality of the roundabout itself and increasing the traffic capacity when compared to their signalized counterparts. This type of design can improve pedestrian safety since pedestrian traffic interferes less with the operation of the intersection. In some cases, an island is employed, allowing pedestrians to cross one lane at a time. In general, pedestrians see a significant reduction in crashes at roundabouts. Studies in different countries have yielded similar results. On average, converting a traditional stop sign controlled intersection or a signalized intersection to a modern roundabout results in a 30%–50% reduction in pedestrian crashes. A Swedish study of “all” modern roundabouts in the country around the year 2000 showed that single-lane roundabouts are about 80% safer than traditional intersections, whereas multilane roundabouts have similar safety level as signalized intersections.

However, there are also some disadvantages to pedestrians. Drivers approaching roundabouts, which are yield-controlled, may slow down but not come to a full stop, and if a driver does not see a pedestrian, they may not stop for them. Therefore, pedestrians cannot be sure that vehicles will not pass over the crosswalk at a certain time. Additionally, the total walking path for pedestrians in the case of a multilane roundabout may be longer than at a signalized intersection since lanes often are 4.25 m wide rather than 3.5–3.75 as common at signalized intersections with bulb-outs. However, many signalized intersections have three or more approach lanes and sometimes even a parking lane extending all the way to the crosswalk. Moreover, visually impaired pedestrians may find it challenging to find the location of the crosswalks due to being generally located far from the usual location at a traditional intersection. Measures such as pedestrian signalization or a raised crossing may be needed in some cases. In general, if approach speeds for the fastest motor vehicles exceed 30 km/h (20 mph) the crosswalks should be raised, but that is the case for traditional non-signalized intersections as well.

Roundabouts reduce the number of potential conflict points for pedestrians for certain movements compared to other types of intersections. These conflicts include conflicts of pedestrians with high-speed vehicles, conflicts of pedestrians with right-turning

Figure 5 Vehicle/pedestrian conflict points for four-leg intersection with one- and two-lane approaches.

vehicles, and conflicts of pedestrians with left-turning vehicles. One-lane roundabouts produce 8 vehicle/pedestrian conflict points compared to 24 for a traditional intersection, and two-lane roundabouts produce 16 vehicle/pedestrian conflict points compared to 28 for a traditional intersection (Fig. 5).

Bicyclist Safety

Safety improvements at roundabouts are most evident in the case of vehicles and pedestrians. However, for bicyclists, it depends on the bicycle design treatment at the roundabout. In general, available studies do not indicate that roundabouts provide improved bicyclist safety compared to intersections that employ traditional traffic control, especially when considering multilane roundabouts. In the United Kingdom, the involvement of bicyclists in crashes at roundabouts was found to be 10–15 times higher than the involvement of car occupants after considering the exposure rates (Brown, 1995).

Figure 6 Roundabout with unprotected bike lanes/bike track.

There are different alternatives to deal with bicyclists at roundabouts. One alternative handling a bicyclist is to have it be treated like a vehicle. In this case, no bike lanes or tracks are provided, and bicyclists use the same lanes as other vehicles through the roundabout. As a result, they have to deal with the same potential conflicts as other vehicles. This option can be used in the United States since bicycles in most states are considered to be vehicles. In this case, bicyclists ride through the roundabout the way other drivers do. They should use the full lane, just like any other vehicle. Accordingly, drivers of motor vehicles have to yield to bicycles when entering, as if bicycles were any other vehicle on the road.

In this scenario, crashes are often due to a bicyclist misusing the roundabout and staying at the right edge of the roundabout and riding alongside vehicles. As a result, they risk having a collision when they circulate by an exit lane. Another crash scenario occurred when a vehicle is trying to pass bicyclists as if they were in a bike lane. This alternative is more suitable for one-lane roundabouts in low-volume environments, as speeds are reduced and the number of conflict points is low. In the case of multilane roundabouts, bicyclists may need another treatment.

For this alternative, if the bicyclists are not comfortable to go through the roundabout on their bikes as a vehicle, they should be allowed to walk or ride their bicycles on the sidewalk. To accommodate this type of movement, a ramp can be installed when approaching and leaving the roundabout to give bicyclists easy access to the sidewalk. In this case, in most jurisdictions, a bicyclist is required to get off his or her bicycle and to cross the travel lanes as a pedestrian. As a result, they have to deal with the potential conflicts for pedestrians.

A second alternative is to have an unprotected bike lane. This type of bike lane is provided in the roundabout adjacent to the travel lanes. In this case, bicyclists and vehicles have separate lanes without a physical barrier except at the four corners (**Fig. 6, left**). This method causes high-risk conflicts between bicyclists inside the roundabout and vehicles turning right to exit. Regarding the effects on all injury crashes, this alternative is considered the worst ([Daniels et al., 2008](#)). In the case of unprotected bike lanes, bicyclists have to give way to vehicles entering and exiting the roundabout. Therefore, bicyclists have minimal effect on the capacities and delays at the roundabout.

This alternative, riding on the edge of a roundabout, is potentially dangerous for bicyclists because it introduces a scenario where vehicles, especially large trucks, can pass them and crowd them off the lane. Another common type of cyclist-car crash occurs when a vehicle either enters or exits from the roundabout without yielding to a bicycle already in the roundabout.

A third alternative (**Fig. 6, right**) is to construct a separate bike track, which is a path that runs separately from the roundabout. The bike track is built outside the intersection, forcing bicycles to cross the path of vehicles outside the roundabout. It can be separated from the travel lane and sidewalks using curbs. In the case of a low pedestrian volume, striping may be enough to separate the bike lane from the pedestrians. Separating a bike track from vehicles using striping only is still used in some places, especially in the United States. In such cases, bike lane delineators (plastic poles with reflectors) are usually added to prevent drivers from driving in the bike lane and to improve visibility in the case of poor lighting or bad weather.

To accommodate crossing, ramps are installed to allow bicyclists to cross the different approaches when circulating the roundabout. Consequently, the number of conflicts between bicyclists and vehicles should decrease as both bicyclists and vehicle drivers are better aware of the presence of each other at the roundabout. In some countries, bicyclists crossing an approach have the priority over the drivers entering and exiting the roundabout, which may affect the capacities and delays at the roundabout.

A fourth alternative is to provide bicyclists with grade-separated bike paths in the form of bike tunnels or bridges. This method is considered the most expensive solution. However, it ensures the elimination of any conflicts between bicyclists and vehicles. Furthermore, bicyclists have no effect on the capacities and delays at the roundabout. This is the standard solution outside urban areas in Scandinavia.

In summary, if providing grade separation is not feasible, the safest approach for accommodating bicycle travel at a roundabout is a bike track, especially in countries where bicycle volumes are high such as Sweden and the Netherlands. In this case, clear yield lines should be provided not only at the roundabout entry but also just before the bike track, both on the entry and on the exit lanes to remind drivers to yield. However, due to the right-of-way needed, this is not a possible option at all roundabout locations.

In countries with low bicycle traffic volumes such as the United States, the primary recommendation is not to have bike lanes at a roundabout. In this case, the bike lanes are terminated some distance prior to the roundabout, and bicyclists have the option to use the travel lane as a vehicle or use the sidewalk if not comfortable to use the travel lane.

Conclusion

Roundabouts are characterized with significant design features to reduce vehicle speed such as the use of a central island, the right angle connection between roadways and circular roadways, and the right of way traffic arrangement, which serves to reduce crash rates and to reduce speed significantly in the area of the intersection. Compared to other types of intersection control, roundabouts eliminate some conflict types, reduce conflict points, and oblige drivers to decrease their speed through the roundabout.

Converting a signalized intersection into a roundabout typically results in a considerable decrease in the number of crashes and specifically crashes with injuries. This is due to the reduction in the number of conflict points, reduction in speeds, which are typically higher at signalized intersections, and the safer environment for pedestrians since they have few directions to check for vehicles than they do at signalized and non-signalized traditional intersections. Similarly, one-lane roundabouts produce greater safety benefits than multilane roundabouts due to the few potential conflicts between road users, shorter crossing distances for pedestrians, and on average lower speeds.

The modern roundabouts are the most commonly used type of roundabout. In recent years, different studies pointed out that there is a need to improve the traffic safety characteristics and to increase the capacity of modern roundabouts. For this reason, there was a need for different solutions to improve these existing roundabouts. Nowadays, many additional types of roundabouts are widely used at different levels within the road network. The flower and turbo roundabouts are two other types of roundabouts proposed to overcome some of the shortcomings of the modern roundabouts.

From the design perspective, the most straightforward design is the modern roundabout followed by the flower roundabout then the turbo roundabout, which requires a more sophisticated design. The main advantage of a flower roundabout is the possibility of building it within an existing modern roundabout without the need to modify the central island or splitter islands, unlike the turbo roundabout. From the capacity perspective, modern two-lane roundabouts can represent an appropriate design solution when high capacity is needed. The flower roundabout can be beneficial when the right-turning volume is high. The turbo roundabout has the advantage of accommodating high traffic volumes for specific directions using different designs of the circular island.

From the traffic-safety perspective, the safety levels of the multilane modern roundabout are considered the lowest. The flower roundabout has some advantages over the turbo roundabout. When converting a modern roundabout to a flower roundabout by separating the right-turning movement from other movements, a two-lane roundabout is transformed into a one-lane roundabout. Consequently, there are less merging and diverging conflict points, no weaving conflict points as in modern roundabouts, and no crossing conflicts as in turbo roundabouts. The turbo roundabout also offers high levels of safety by improving deflection and reducing the number of conflicts.

There are indications that pedestrians are safer at roundabouts compared to other types of intersections if pedestrian crosswalks are provided around the perimeter of the roundabout. The number of conflict points is less, splitter islands allow pedestrians to cross one direction at a time, and the low vehicle speeds through a roundabout allow more time for drivers and pedestrians to react to one another. As a result, few pedestrian crashes are usually found at roundabouts. For bicyclists, there is no clear evidence of the safety benefits for roundabouts over other types of intersections. Furthermore, there is no final evidence regarding the safety benefits of the different types of bicycle treatment. However, there are indications that roundabouts with bike tracks are safer than roundabouts with mixed traffic or unprotected bike lanes.

The Intention With Rumble Strips

Driver fatigue, including both sleepiness-related and task-related underload and overload situations, is considered as a contributing factor in approximately 20% of all vehicle crashes, the view is the same for inattention. Rumble strips in the center of two-lane rural roads and on the shoulders of motorways as well as two-lane roads are a countermeasure aimed to help drivers who unintentionally are leaving the lane, for example, due to sleepiness or inattention.

The thump of the rumble strip is aimed to give the driver feedback in time to be able to react and take action to avoid running off the road or collide with on-coming vehicles. The rumble strip should be designed to support the drivers, without threatening them. In addition, they should give a clear feedback and not causing dangerous erratic maneuvers. They also need to be detectable for all kind of drivers like that of passenger cars, trucks, and buses; and at the same time not causing problems for riders of motorbikes, cyclists, or pedestrians.

In this chapter, we aim to summarize the knowledge about rumble strips on rural roads and their design, their effect on road users, and their general impact.

Different Designs and Placements of Rumble Strip

Rumble strips across the traveled roadway ahead of crosswalks, stop signs, and toll plazas have been used—in limited quantities—for at least 50 years. The intent of those is to get a driver's attention and signal that something unexpected is coming up. However, this article is limited to looking at more-or-less continuous rumble strips along a roadway. Experiments with such rumble strips started in 1950s and they have now been used widely in several countries for decades, especially in the United States and Canada. Sometimes they are installed in raised profile and sometimes as in-ground (milled or pressed). Variation is not only between raised versus in-ground rumble strips but also in their width, depth, length and design.

Rumble strips installed in raised profile typically has the aim to increase the visibility of the road marking during wet conditions at nighttime. The secondary effect of such installation, in terms of internal noise and vibrations, disappear after a short time and is not even possible to detect in heavy vehicles, such as trucks and buses.

Rumble strips are normally used on the shoulder or in the center of the road. The design of them might differ dependent on if they will be driven on frequently or not, since external noise is an important factor and more noise-friendly solutions are required if drivers are expected to drive across them frequently, especially if they are located near residential developments. Designs of in-ground rumbles strip causing less noise have been developed during the past few years.

In Fig. 1 two different examples of in-ground centerline rumbles strips are shown. One is the conventional one and other, with the same depth, has a sinusoidal design in order to reduce the level of external noise. They both are using a design that in Sweden is called Målilla, that is 0.35 m wide, 0.50 m center to center, and with a depth of approximately 1.0 cm.

In some countries, for example, Norway and Finland, the center of the road is equipped with two road markings with one or even two in-ground rumble strips in between them.

Figure 1 (A) Swedish Målilla design in road center. (B) Swedish sinusoidal Målilla design in road center.

The sinusoidal in-ground rumble strips are also used on shoulders. In Norway, the recommendation is to use those and apply the road marking in the rumble strip. Such a solution protects the road marking, which normally suffers from maintenance work during wintertime. The Norwegian recommendation of width of the rumble strip is 40 cm with a road marking of 10 cm or 55 cm, if the width of road marking is 15 cm (Høye, 2015).

The in-ground rumble strip generates both an internal noise and a sensation of vibrations. Most studies on internal noise have focused on passenger cars. The results show an increase in internal noise when driving on intermittent rumble strips that varies between 13 and 17 dB(A). For the sinus rumble strip, the corresponding values are 1–6 dB(A). Whether the level of signal obtained for the sinus rumble strip design is enough in order to attract the driver's attention is as far as we know not evaluated. However, results from simulator studies show that even low levels of internal noise are helpful for drivers who are about to leave the lane due to sleepiness. The sinus rumble strips provide not only noise but also vibrations. What the most important component to attract attention is not known, but it is most likely that the vibrations create an important contributing effect. There are almost no studies available on the effects on drivers of trucks and buses. In the studies done 20 years ago, it was highlighted that internal noise driving on rumble strips varies a lot depending on the type of truck or bus and for trucks it was highly dependent on the vehicle type and cargo. It was also shown that truck cabs often are so noisy that the vibration is a necessary part in waking dozing drivers, and that the rumble strip indentation must be significantly wider than the truck tire to get the full effect of vibration.

An alternative placement of rumble strips on rural roads is in the center of the lane. This has been tested on narrow roads in Sweden and also in the United States. The intention was to avoid rumble strips both on the shoulder and in the center of the road (Fig. 2). The evaluation showed that the solution itself might be good, but that the road included in the tests were too narrow (6.5 m) with major complains from users, especially motorcycle riders and truck drivers that argued the solution limited their right to use the lane and that in case of sleepiness there were too little time left to counteract the lane departure.

On motorways, and where drivers are not expected to cross them, it is common to use a deeper in-ground rumble strip. One type often seen, both in the United States and in Europe, is the so-called Pennsylvania rumble strip. This is a rumble strip with a depth of 1.2 cm, a width of 30–50 cm, a length on 13 cm with a center-to-center distance of 30 cm. They could be used both continuously or intermittent as in Fig. 3. This is the far most common design and the recommendation in, for example, the Swedish road construction directives for motorways.

Rumble Strips Effect on Driver Behavior and Driver Performance

Drivers are influenced by the rumble strips not only when passing over them but also when they are driving. In general, they seem to reduce their speed with 2–5 km/h, also increase the distance to them with 10–15 cm, and also contribute to a variability of the lateral position (Vadeby and Anund, 2017). This means that they might have an impact also when not used for alerting drivers. The increased variability on lateral position might have a negative impact on maintenance in terms of increased rutting and wear but also causing closer interactions with pedestrians and cyclists. In Norway, this has led to a recommendation to not use centerline rumble strips on roads that are narrower than 7.5 m. Additionally, in Sweden, the Road Construction Directives recommends that two-lane

Figure 2 Swedish conventional Målilla design in lane center.

Figure 3 (A) Pennsylvania design—intermittent on motorways shoulder. (B) Pennsylvania design—continuously on motorways shoulder.

roads with a width of 7 m or more should have in-ground rumble strips. If this is fulfilled, the speed limit is set to 80 km/h. Hence, the prevalence of rumble strips is highly related to the speed of the road.

A sleepy driver that hits a rumble strip will be alerted even though the rumble strip itself is not very deep. However, it must be kept in mind that the effect of the rumble strip in time is very short. Studies in simulators show that already 5 min before a rumble-strip hit on motorway, the drivers show signs of severe sleepiness. After the hit they are alerted to the same level as in the beginning of the drive, but after another 4 min of driving, they are no longer significantly alerted (Anund et al., 2008). This means that it is important to understand that hitting a rumble strip in a sleepy condition is a very late warning that require a stop for rest as soon as possible in order to avoid risky driving. In addition, there is support for any adverse effect in terms of crash migration from locations with to those without rumble strips. In other words, if motorways have shoulder rumble strips and secondary roads do not, crashes may migrate from the motorway—that typically has safe roadside areas—to the secondary road that may have trees or other obstacles near it (Smith and Ivan, 2005).

The Impact of Rumble Strips

Traffic Safety

Centerline rumble strips have been shown to reduce the number of single-vehicle crashes and crashes with oncoming vehicles, thereby reducing the number of crashes, fatalities, and injuries. The traffic safety effect may vary between different countries depending on the configurations used. A common effect is estimated to about 10% reduction of all injury crashes and 37% reduction of target crashes (head-on, single-vehicle crashes to the left etc.). The estimated effectiveness of centerline rumble strips on two-lane carriageways differs dependent on crash severity and crash type, within a range of approximately 10%–50%. In [Table 1](#), an estimate of the traffic safety effect can be found. The results are based on almost 20 studies and reported in *The handbook of road safety measures* (Elvik et al., 2009; Gårder and Davies, 2006).

Studies from the United States show a reduction in the total number of crashes by, on average, 9% and that fatal and injury crashes are reduced by about 12%. Looking at the target crashes only, a 30% reduction was seen in head-on and opposing direction

Table 1 Traffic safety effects of milled rumble strips

<i>Centre-line milled rumble strips</i>		
Crash type and injury level	Effect (%)	Confidence interval (95%)
All injury crashes	−10	(−14; −5)
Target crashes ^a , all injury	−37	(−42; −31)
<i>Centre-line and edge-line milled rumble strips</i>		
Crash type and injury level	Effect (%)	Confidence interval (95%)
All injury crashes	−14	(−23; −3)
Target crashes ^b , all injury	−32	(−36; −29)

^aHead-on, run-off-the-road to the left, side-collisions in opposite direction.

^bHead-on, run-off-the-road to the left/right, side-collisions in opposite direction.

sideswipe crashes, 25%–30% reduction in injury crashes while fatal crashes were reduced by 44% (Russels and Rys, 2005). In Western Australia, a quasi-experimental study resulted in a reduction in the all-severity crash rate of 58% and in casualty crashes of 80%. In Sweden, milled centerline rumble strips have been shown to reduce the number of severely injured in all crash types by 15% and by 24% in single-vehicle crashes. No significant changes were noted for “all injury crashes.” In Norway, installing milled centerline rumble strips resulted in a reduction in injury crashes. Head-on crashes were reduced by 32% and single-vehicle run-off road to the left by 54%.

Most of these studies consider a mixture of raised and in-ground rumble strips and include variations in the type of in-ground rumble strips as well as a variation of the environment where the road is located. These heterogeneities are confounding factors that cause limitations especially in estimating the optimal effect. A study from Norway including large-scale reports of real-world driver experiences supports the evidence that rumble strips reduce crash numbers and reduce the severity of consequences, specifically of fatigue-related driving; and they found a significant reduction in sleep-behind-the-wheel incidents resulting in road departure crashes when rumble strips were present.

Negative Effects of Rumble Strips

External Noise

In Denmark, Norway, and Sweden, measurements were made of the maximum external noise in the vicinity of rumble strips. There were major variations in results for both intermittent rumble strips and sinus rumble strips. The results show that the intermittent rumble strips provide an increase of external noise of around 2–8 dB(A). The corresponding figure for the sinus rumble strip was 0.0–4 dB(A). Further, it was found that the sinus rumble strips provide more low frequency noise (30–40 Hz) compared to the intermittent rumble strips (60–160 Hz). Maximum noise from intermittent rumble strips are obtained at around 80–90 km/h, and at 90 km/h the threshold for noise for those living close to the road is 90–140 m. It is not known at what speed the sinus rumble strip provide the maximum noise. There is reason to believe that what is perceived as disturbing is not only related to the maximum noise but rather to the fact that the sound deviates from the normal monotonous traffic noise. The rumble-strip sound is more low frequency and not continuous.

Surface

The introduction of centerline rumble strips can result in traffic confinement and cause a reduction in the amount vehicle wander laterally. This reduction is likely to increase the rate of rutting. A Swedish study investigated how annual rut development rates and rut area measurements on two-lane rural roads were affected by the introduction of milled centerline rumble strips. Comparisons between the test sections with milled rumble strips and control sections without them, showed that there were no major differences in rut development rates. The conclusions to be drawn from the results are that centerline rumble strips do not have a noticeable confining effect on traffic and have no adverse effect on the rate of rutting.

Effect on Safety and Comfort for Vulnerable Road Users

Motorcycle riders are normally sensitive to countermeasures on roads that might limit their use of the full road. However, several tests have been carried out where riders were involved and as long as rumble strips are not too deep and used as transverse strips across the road direction, there are no major complains, except if they are in the center of the lane. Studies from New Zealand and the United States has shown that the rumble strips have not been a contributing factor in crashes with motorcycles and that the rumble strips have very small impact on the stability of the motorcycle. Studies also shows that motorcyclists, in general, do not experience any significant negative effects of the rumble strips, as long as they are aware of that the road has rumble strips.

Centerline milled rumble strips can indirectly affect the safety of bicyclists due to that vehicle drivers tend to change their lateral position toward the right when there is a rumble strip in the center, leading to less available space for cyclists. This is a problem that has been raised especially in the United States where separate bicycle facilities seldom are provided, and bicyclists typically use the edge of the travel way or narrow shoulders (Gårder and Davies, 2006).

Maintenance

When rumble strips were first installed, there were worries that if they were not in-ground, the effect of them in terms of vibrations and sound would disappear after a winter of plowing snow. This was a correct reflection and an argument for the use of in-ground rumble strips.

There was also criticism that in-ground rumble strips would create a problem in snow plowing in winter when it would be difficult to clear snow in an optimal way using the wing of the plow. However, this has not been proved to be a problem. In order to extend the lifespan of rumble strips and to avoid cracking formation in the roadbed, it is usually required that the in-ground rumble strips should be sealed in connection with milling. It is difficult to find studies on cost-benefit analysis of the rumble strip taking all positive and negative impacts into consideration. However, milling or pressing in-ground rumble strips do not require any specific equipment besides the machine and is therefore a much cheaper solution as compared to, for example, guardrails or wire barriers, etc. An additional advantage is that rumble strips can also be used on more narrow roads where guardrails and wires will not be possible to fit.

Conclusions

Rumble strips save lives at a rather small cost in relation to other infrastructure-based countermeasures, they can be used on most roads including narrow ones, and they are effective for all drivers regardless of type of vehicle. The aim that rumble strips should help drivers who unintentionally are about to leave their lane, for example, due to fatigue or inattention are proven to be achieved. Despite, variations in design evaluations, they are typically shown to reduce all injury crashes by about 10% and target crashes (head-on, single-vehicle crashes to the left, etc.) by about 37%. Rumble strips contribute to a speed reduction of 2–5 km/h and an increased distance to them of 10–15 cm, something that is good for vehicle-to-vehicle interactions, but less good for pedestrians and cyclist using the shoulder. The in-ground strips do not cause problems for maintenance during wintertime or to the road construction itself and as long as they are sealed, they will remain in good shape for a long time.

Introduction

Transport is fundamental to our society, but it unfortunately has several negative side effects. The annual number of road traffic fatalities is now 1.35 million people, while between 20 and 50 million people sustain nonfatal injuries (WHO, 2018). Thanks to safety strategies targeting general road user safety behaviors, as well as improvements in technology and infrastructure, the number of road fatalities has steadily decreased. For example, in the United States, fatality numbers in roadway traffic peaked in 1972 with 54,589 people killed and was reduced to 37,133 in 2017 while the population grew from 209.9 million to 325.7 million, bringing the fatality rate from 260.1 to 114.0 fatalities per million inhabitants, a reduction in the rate of 56%. Even more impressive, in Sweden, the total number of people killed in roadway crashes has gone from a high of 1313 in 1965 (and stayed the same in 1966) to 253 in 2017 in spite of the population growing from 7.77 to 9.95 million; it means that the fatality rate per million people has decreased from 168.9 to 25.4 in this period, a rate decrease of 84.9%. To reduce road crash risks for all road users further, it has been argued that new perspectives are required, and international research has pointed to safety culture as a promising new perspective (AAA, 2007; Ward et al., 2010, 2019). Safety culture generally refers to shared and safety relevant ways of thinking or acting that are (re)created through the joint negotiation of people in social settings.

Since its first use in the wake of the Chernobyl nuclear power accident in 1986, the organizational safety culture concept has become an established part of safety research. Although it has especially been applied in what is considered high-risk settings like the nuclear industry and in aviation, the relationship between organizational safety culture/climate and safety outcomes is robustly documented in studies reporting experiences across organizations, industries, and countries (Christian et al., 2009; Zohar, 2010). The crucial importance of safety culture is also documented in a range of accident investigations. Additionally, high-quality studies of safety culture interventions, with pre- and post-measurements, test, and control groups, have indicated up to 60% decrease in crash risk in the road sector (Nævestad et al., 2018a).

In spite of this, the organizational safety culture perspective has been applied to a limited extent among drivers at work in general and professional drivers in specific. Potential reason for this is the lack of rules requiring safety management systems (SMSs) in the sector. SMS typically includes formal routines and measures enabling the organization to work systematically with safety, by identifying and correcting risks, for example, appointment of key safety personnel, risk assessments, safety training, safety procedures, and safety performance monitoring. SMSs aiming to foster positive safety culture are legally required in aviation, rail, and the maritime sector. In contrast to the other transport sectors, formal SMSs for companies in the road sector are so far voluntary (e.g., ISO:39001). While SMS denotes the formal aspects of safety management in organizations ("what the organization is supposed to do"), safety culture denotes the informal aspects ("what the organization actually does") (Antonsen, 2009). Other factors that may explain the presumably lower focus on organizational safety culture in the road sector are the prevalence of small road transport companies that often have few resources and lower competence on organizational safety management, and that drivers at work often are treated in the same ways as private car drivers, by their companies and authorities. The latter means that drivers at work are given the primary responsibility for the safety of their driving, often neglecting the organizational influence on, and responsibility for their safety performance. This contrasts with Vision Zero, which fits well with a safety culture perspective (refer to Article The Swedish Vision Zero – A Policy Innovation).

When employing the safety culture concept to road transport, it is important to note that the organizational safety culture concept only applies to drivers who are part of work organizations. Given the potential importance of the safety culture perspective for road safety, and the fact that the majority of drivers on the road are not at work, several scholars have also argued that the safety culture perspective should be employed to private road users, linking it to other social units than organizations, for example, nations, communities, peer groups, and families (Edwards et al., 2014; Luria et al., 2014; Nævestad and Bjørnskau 2012; Rakauskas et al., 2009). We will return to this issue later.

What is Organizational Safety Culture?

The concept of (safety) culture lends itself to a wide range of different definitions and operationalizations, as it is abstract and general. A 1963 study conducted by Kroeber and Kluckhohn referred to more than 160 definitions of culture. As a consequence, safety culture is often criticized for being a fuzzy concept that refers to everything and nothing. Researchers have pointed to a fragmented literature and terminological confusion within safety culture research (Antonsen, 2009; Glendon, 2008; Guldenmund, 2000). Nevertheless, most researchers agree that safety culture is a sub-concept of the more general concept of organizational culture, and thus that safety culture can be described and understood by referring to definitions and conceptualizations of organizational culture (Edwards et al., 2014). The highly influential organizational culture scholar and social psychologist Edgar Schein defines organizational safety culture as:

“(. . .) a pattern of shared basic assumptions that was learned by a group as it solved its problems of external adaptation and internal integration, that has worked well enough to be considered valid and, therefore, to be taught to new members as the correct way to perceive, think, and feel in relation to those problems.” (Schein, 2004, p. 17)

Drawing on a sociological/social anthropological understanding of culture, Stian Antonsen refers to culture as:

“(. . .) frames of reference through which information, symbols and behavior are interpreted, and the conventions for behavior, interaction and communication are generated.” (Antonsen, 2009, p. 4).

Bearing these definitions in mind, organizational safety culture can be defined as “safety relevant aspects of culture in organizations.” The important thing to remember about these definitions is that safety culture provides frames of reference that guide individuals’ interpretations of actions, hazards, and their identities, and which motivate and legitimize behaviors that have an impact on safety, and that such shared frames of reference are created through interaction within groups.

It should also be mentioned that several scholars on culture in organizations discern between different levels of culture. Schein discerns between three different levels. Culture at the deepest level refers to underlying assumptions (beliefs, perceptions, thoughts, and feelings) influencing what we pay attention to, what things mean, how we react emotionally, and how we act. Organizational culture at the middle level refers to espoused beliefs and values, for example, explicit strategies, goals, and philosophies, while organizational culture at the most superficial level refers to artifacts, for example, visible organizational structure and processes. Accident investigations often find discrepancies between cultural levels, for example, between espoused values (e.g., safety first) and underlying assumptions (e.g., timetables must be met).

Due to the safety performance and acknowledged good safety culture of aviation, James Reason’s description of five key aspects of safety culture (based on aviation) is often used as a point of departure for describing the most important aspects of good safety culture (Reason, 1997). First, Reason refers to a good safety culture as an informed culture, which means that the organization collects information about both accidents and incidents and carries out proactive countermeasures. The second aspect is a reporting culture, which means that all employees report their errors or near misses, and take part in initiatives to improve safety. The third aspect of safety culture is a just culture, which means that there is an atmosphere of trust within an organization that encourages and rewards its employees for providing information on errors and incidents, with the confidence of knowing that they will receive fair and just treatment for any mistake they make. A just culture is a key premise of a reporting culture. The fourth aspect is a flexible culture, which involves that the organization and its members are capable of adapting effectively to changing demands. The final aspect of safety culture is a learning culture, which means that the organization learns from incident reports, safety audits, and so forth, resulting in improved safety. These aspects of good safety culture are by and large taken for granted as the key aspects of good safety culture in all sectors, including transport, for example, in rail, in maritime sector, and in road.

How Can Safety Culture Be Measured?

Safety culture, exemplified by Reason’s key aspects, can be studied using a qualitative or a quantitative approach, or ideally through a combination of the two. These methods facilitate examinations of different aspects and layers of safety culture. Quantitative studies are often referred to as studies of safety climate, which can be conceived of as “snapshots,” or manifestations of safety culture (Flin et al., 2000). Safety climate is also defined as perceptions of the value and importance of safety in a given context. The concepts of culture and climate are, however, often used interchangeably. Based on Schein’s depiction of different layers of culture, we may state that safety climate only gives access to the most superficial levels of safety culture: perceptions of managers’ and colleagues’ commitment to safety, perceptions of incident reporting, perceptions of procedures, safety training, etc (Guldenmund, 2007). Quantitative measurements of safety culture can provide leading indicators of safety and consequently offer predictive assessments that enable safety improvements without having to wait for crashes or incidents to happen. Quantitative measurements of safety culture are necessary to compare scores over time between organizations and to quantify the relationship between safety culture and safety outcomes.

The most commonly measured aspect in safety climate studies, independent of sector, is senior management commitment to safety. This is the most studied and best-documented characteristic of a good safety climate. It tends to influence all other safety-related

aspects of organizations (Flin et al., 2000). The other most commonly measured aspects of safety climate, independent of sector, are employee perceptions of SMSs (e.g., work permit systems and safety philosophies) and perceptions of, and attitudes to, risk.

Risking oversimplification, we may suggest that while safety climate often is studied quantitatively by social psychologists, safety culture is often studied qualitatively by social anthropologists and sociologists. The qualitative studies involve research interviews and/or time-consuming fieldworks, where researchers interact with people over long periods of time to learn how they see the world, how they think, how they (inter)act, etc. Qualitative studies of safety culture focus on how it guides individuals' interpretations of actions, hazards, and their identities, and motivates and legitimizes behaviors that have an impact on safety. These studies may give us access to the "deeper" levels of safety culture: the more implicit and taken-for-granted basic assumptions and "tacit knowledge." Qualitative studies focus on how safety culture provides a frame of reference that guides individuals' interpretations of actions, hazards, and their identities, and which motivates and legitimizes behaviors that have an impact on safety.

Organizational Safety Climate among Drivers at Work

There are few studies focusing explicitly on organizational safety climate among professional drivers, or drivers at work in road transport. The studies that do exist often combine organizational safety climate questionnaires with questionnaires measuring safety outcomes such as self-reported driving behaviors (e.g., the Driving Behavior Questionnaire [DBQ]) (Reason et al., 1990) and self-reported crashes (Davey et al., 2006; Öz et al., 2014).

Apart from also focusing on management commitment to safety, like most of the studies of safety climate independent of sector do, the studies of safety climate in road transport organizations also measure safety climate aspects such as, for example, the supervisor's role (adequacy of), fleet safety rules, support from managers and supervisors during the trips, communication and support, work pressure, driver training, colleagues' influence, competence, etc (Davey et al., 2006; Huang et al., 2013; Wills et al., 2005). The studies also often include questions on perceived time and work pressure, and other work-related factors related to efficiency, for example, commission pay, bonus, and reward systems. The studies also include questions measuring attitudes to various traffic safety interventions targeting risky behaviors, perceptions of risky behaviors, and so forth. Although management commitment, perceptions of SMS aspects, and work pressure are recurring safety climate aspects measured in the studies, this indicates the abundance of possible safety climate aspects. As in studies of safety climate in other sectors, it may be difficult to replicate factor structures in different organizational settings.

The existing studies generally find that positive organizational safety culture/climate scores are related to lower incidences of aberrant driving behaviors, measured by means of the DBQ. The DBQ originally distinguishes between three types of aberrant behaviors, based on Reason et al. (1990): lapses, errors, and violations. Lapses typically involve problems with attention and memory. Errors typically involve observation failures and misjudgments. Violations involve deliberate deviations from safe driving practices. The aberrant driving behaviors that have been found to be related to organizational safety culture/climate are violations and errors.

Studies of safety climate/culture in road transport also find a relationship between organizational safety culture/climate scores and crash involvement among professional drivers and drivers at work. As noted, high-quality studies of safety culture interventions, with pre- and post-measurements, test, and control groups, have indicated up to 60% decrease in crash risk (property damage accidents) in the road sector. Retrospective data indicate that an annual average of about 1.500 people in Norway are injured in accidents involving drivers at work annually, and most (81%) of the people injured in these accidents are other road users. At the same time, Norwegian and international research indicates that companies employing drivers at work often focus (too) little on organizational factors such as safety culture and SMS. Estimates including only road goods transport companies in Norway indicate that between 7 and 56 fatalities/severely injured potentially could have been avoided annually, if those companies had focused systematically on safety culture and SMS (Nævestad et al., 2018b). The estimates take into account prevalence, expected effects, etc. These estimates are conservative, and they only apply to about 40% of the accidents involving drivers at work in Norway. Thus, there is a large and largely untapped safety potential in focusing on safety culture and SMS in transport.

The relationship between safety climate/culture and crashes often seems to be mediated by driving behaviors, for example, measured by means of the DBQ. Studying the relationship between organizational safety culture and crashes is, however, not a straightforward issue, as it may be difficult to determine the causal relationship between safety culture and crashes. First, reporting of errors, injuries, crashes, etc., is one of the key characteristics of good safety culture. Thus, organizations with a good safety culture will also have a higher probability of reporting a high number of crashes, injuries, and incidents. (Still, police reported injury crashes would be relatively unbiased.) In organizations with poorer safety culture, on the contrary, we may expect a certain level of underreporting of incidents. Second, cross-sectional studies of safety culture and crashes may also find a negative relationship, e. g. if organizations have learned from crashes and developed a positive safety culture. Nevertheless, high-quality studies of organizational safety culture in road transport also indicate that good safety culture/climate is related to fewer crashes.

Safety Culture among Nonprofessional Road Users

It seems even more important to employ the safety culture perspective to nonprofessional road users, as these include high-risk groups, like those who are too young or too old to be employed by work organizations, and which also include drivers who drive in

high-risk contexts, for example, in weekend, at evening/nights, and with friends (Luria et al., 2014). Few studies have, however, so far been devoted to this issue. Employing the safety culture concept to these groups involves, however, shifting the focus to other social units than organizations, for example, nations, communities, peer groups, and families (Edwards et al., 2014; Luria et al., 2014; Nævestad and Bjørnskau, 2012; Rakauskas et al., 2009). There are several challenges related to this, as some sociocultural units may be less well defined than, for example, work organizations (Nævestad and Bjørnskau, 2012).

Although scholars seem to agree that safety culture is also important for nonprofessional road users, there are still no definitions of traffic safety culture that are commonly accepted by road safety researchers (Edwards et al., 2014; Girasek 2012). Previous studies of traffic safety culture among private drivers define it as, for example, the “beliefs, norms and values and things people use that guide their social interactions in everyday life,” “implicit shared values and beliefs,” and “common practices, expectations and informal rules that drivers learn by observation from others in their communities (Edwards et al., 2014).”

There seems to be agreement that traffic safety culture among nonprofessional road users can be viewed as a different application of the same foundational concept as organizational safety culture (Edwards et al., 2014). Thus, we may, for example, define safety culture among nonprofessional road users as, for example, shared norms, beliefs, and assumptions that provide frames of reference that guide individuals’ interpretations of actions, hazards, and their identities, and which motivate and legitimize behaviors that have an impact on safety, and which are created through interaction within groups. We may hypothesize that this definition also can be applied to the national level, the community level, peer groups, and families.

Safety culture is generally (re)created through interaction processes in groups, and, to explain the existence of traffic safety culture at different levels (e.g., national, communities, peer group, and family), we may hypothesize that this interaction is influenced by factors located at different analytical levels. At the more general level, we may hypothesize that national road safety culture is created through processes involving drivers in the same country. Several factors that could influence a traffic safety culture are national (e.g., traffic rules, the police enforcing the rules, and infrastructure). Based on these factors, we may expect the existence of different national traffic safety cultures. Studies comparing road safety in countries find considerable variations between national road safety records (the fatality risk varies with a factor of up to 10 between EU countries), and between self-reported road safety behaviors, measured by means of the DBQ. In accordance with this, studies find national differences between national traffic safety cultures. A recent study comparing national traffic safety culture among Norwegian and Greek private and professional drivers found a relationship between national traffic safety culture and driver behaviors, which in turn were related to self-reported accident involvement (Nævestad et al., 2019). The authors found that the differences were in accordance with the national road safety records in the two countries. This study defines road safety culture as shared patterns of behavior, shared norms prescribing certain road safety behaviors, and shared expectations regarding the behaviors of others. The study measures national traffic safety culture as descriptive norms, hypothesizing that the mechanisms between national traffic safety culture and road safety behavior are drivers’ perception of what is “normal” and expected from drivers within their country, generating a subtle social pressure to behave in certain ways. This hypothesized mechanism may explain the influence of road safety culture in several different groups (national, community, peer groups, and family) on behaviors, and we may hypothesize that the perceived social pressure is stronger, contingent on the importance of the group (e.g., that family and peers are most important).

It also seems well founded to hypothesize the existence of traffic safety culture at the community level, as road user interaction to a large extent occurs between a given number of actors within relatively geographical limited areas (Luria et al., 2014). This especially applies to islands, which to some extent are closed communities. The mentioned study of traffic safety culture in Norway and Greece found such an “island effect”, and a previous study has also found differences between traffic safety culture in rural and urban areas.

Some studies also apply the traffic safety culture perspective to peer groups, which can be defined as a group of people sharing some key characteristics, often a combination of age, sex, and/or crucial interests. This type of sociocultural group membership is hypothesized to be especially important, as its members are assumed to view each other as equal, significant others, who share identities and who often exercise a considerable level of normative pressure to comply with certain norms for behavior. In accordance with this, studies have found descriptive norms at the peer level to influence road user behavior.

Finally, it should be noted that the application of the safety culture concept to nonprofessional road users is less developed than the organizational safety culture concept. The successful application of the safety culture concept to private drivers seems to be contingent on developing more research-based knowledge on: (1) the mechanisms generating traffic safety culture in different sociocultural units (nations, communities, peer groups, and families), (2) a theoretical explanation of the influence of traffic safety culture on traffic safety behaviors in these sociocultural units, and (3) how this knowledge can be utilized to develop successful interventions to improve road safety (Nævestad et al., 2019). We will return to these issues later.

How Can Safety Culture Inform Preventive Measures in the Road Sector?

Approaches to Influencing Safety Culture among Drivers at Work

Although there are few studies of explicit safety culture interventions in the road sector, the research on organizational safety culture stands on the shoulders of the more well-developed organizational culture research. It is therefore easier to describe how this perspective can inform measures to prevent road crashes, than it is to describe how the research on nonprofessional road users can inform preventive measures (as this scarcely has been studied).

Based on existing research, we may conceive of at least three ways of influencing organizational safety culture in organizations employing drivers at work. First, managers may influence safety culture through their daily management of safety culture. Schein (2004) refers to “six primary embedding mechanisms” that managers can use to shape culture:

- 1 What managers pay attention to, measure, and control on a regular basis
- 2 How managers react to critical incidents and organizational crises
- 3 How managers allocate resources
- 4 Deliberate role modeling, teaching, and coaching
- 5 How managers allocate rewards and status
- 6 How managers recruit, select, promote, and excommunicate

Although this probably is the most important way of influencing safety culture, due to its regularity and comprehensiveness (ideally applying to all aspects of organizational life), these mechanisms have, to a little extent, been subjected to robust evaluations in transport. The reason is probably that this mode of influence is constant, indefinite, and hard to delineate and define. It must, however, be noted that the importance of these mechanisms is indicated by the fact that management commitment to safety is the most important aspects in studies of organizational safety climate. The mechanisms specify and operationalize how management may indicate commitment to safety. Several scholars criticize, however, the assertion that leaders initiate and shape integrated organizational cultures in organizations. They hold that culture emerges bottom-up, as cultures are created and recreated through group members’ interaction and negotiation over meaning (Nævestad et al., 2018a). This means that organizations comprise several subcultures that may respond negatively to managerial efforts to manage culture, and that changing and managing safety culture is a very demanding task.

Second, safety culture in organizations may also be influenced by means of interventions. A systematic literature review of safety culture interventions in transport organizations, published in 2018, identifies eight relevant studies of interventions that may be defined as safety culture interventions in road transport organizations (Nævestad et al., 2018a). Generally, the interventions have a broad safety focus, which means that safety culture is not the primary target of the interventions. Effects on safety culture are only measured (or assumed to happen) as an additional effect of a broader set of organizational safety measures. The interventions also vary widely in resource intensiveness. Nevertheless, the author concludes that safety culture interventions seem to be effective, as the most robust of the reviewed studies (with pre- and post-measurements, test, and control groups) indicates that safety culture interventions improve safety culture and safety behaviors, and reduce crashes. However, as the studied interventions often are very different, the author identifies four key elements that seem to be common in all the reviewed safety culture interventions:

- 1 Appointing a key person (generally a manager) to be responsible for implementing the intervention.
- 2 Institutionalizing joint discussions and risk assessments of workplace hazards, involving managers and employees.
- 3 Implementing and monitoring measures based on these discussions and joint risk assessments, for example, reporting systems and training.
- 4 Maintaining effective communication about safety issues in the organization, in line with Reason’s depiction of an informed safety culture.

The authors concludes that the basic requirements of safety culture change seem to institutionalize joint discussions of workplace hazards facilitated by manager commitment and employee involvement.

A third possible approach to influencing organizational safety culture is by implementing SMS. As noted, this is a common strategy in other transport sectors, in which SMS fostering positive safety cultures are required. The 2018 review referenced earlier mentions at least one high-quality study describing how voluntary SMS implementation (ISO:39001) in road transport organization fosters positive safety culture.

Approaches to Influencing Safety Culture among Nonprofessional Road Users

Describing how the safety culture perspective can be used to inform preventive measures among nonprofessional road users is, as noted, a relatively unresearched issue compared to the research on organizational safety culture interventions among drivers at work. One possible approach is to take the knowledge about the factors influencing traffic safety culture in the different sociocultural groups as the point of departure, and to identify how to effectively influence these. In a recent study comparing national traffic safety culture in Norway and Greece, the authors hypothesizes that national traffic safety culture is (re)created through road user interaction, which is influenced by infrastructure, enforcement, training, the composition of road users, and economic conditions (Nævestad et al., 2019). The authors also suggest that national traffic safety culture could be influenced by targeting the five factors influencing the interaction among road users. They argue that relevant questions in this respect are, for example, which factors are possible to influence? (How) do the factors interact? What are the expected outcomes? Which is the most important factor? They also state that a crucial question is the extent to which traffic safety culture is an independent social force, and the extent to which it merely reflects other influencing factors (e.g., infrastructure and enforcement). An important question related to this is the extent to which collectively shared norms for behavior remain unchanged, although the factors through which they originally were influenced by change, or whether shared norms “follow” from infrastructure, police enforcement, and education. We may hypothesize that the interaction between road users creates an independent dynamic where new norms are developed, which not necessarily reflect the infrastructure. Certain social groups may develop norms prescribing unsafe road behaviors, despite good training, infrastructure,

and police enforcement. This discussion and several of the discussed factors (e.g., interaction, enforcement, and infrastructure) are also relevant in the discussion of how to influence traffic safety culture at the community level.

A second and relatively widespread approach that is discussed by the mentioned study, and which already is applied in several countries, is to change traffic safety culture through campaigns aiming to change road users' attitudes, norms, and thus to motivate safe(r) road transport behaviors (Nævestad et al., 2019). Relevant questions in this respect are, for example, how do social norms for road safety behavior come about? To what extent is it possible to change such norms through other ways than the interaction processes in which (we assume) that they are created? How should it be done? Research on road safety campaigns often shows that they are more efficient when they are combined with police enforcement. Thus, future research should also shed more light on such relationships and the combinations of mechanisms generating changes in traffic safety cultures.

A third approach to influencing traffic safety culture among nonprofessional road users, that also is discussed in the aforementioned study of Norway and Greece, is to employ a social norms approach, targeting descriptive norms, that is, perceptions of what other people in a given group do (Nævestad et al., 2019). As noted, the study of national traffic safety culture in Norway and Greece hypothesized that the observed relationship between national traffic safety culture and road safety behaviors could be explained by pointing to descriptive norms, creating a subtle social pressure to behave in certain ways. The underlying idea behind the social norms approach to interventions is that people who behave in undesirable ways (e.g. driving under the influence of alcohol, failing to use seat-belt) tend to overestimate the prevalence of risky behavior among other people (e.g., in their country and in peer groups) to justify their own undesirable behavior (e.g. "everybody drink and drive"). This effect is referred to as false consensus. Thus, the social norms approach hypothesizes that by informing people about the actual prevalence of risky behavior in given groups, the false consensus effect will be reduced or removed, and mild social pressure (i.e., the descriptive norms mechanism) will make people behave in safer ways. This approach has successfully been employed in traffic safety interventions. The social norms approach may, however, not work if road users at risk have fairly correct perceptions of their peers' (un)safe behavior. This could be the case in high-risk subcultures, which may be based on, and defined by, risky behaviors.

Introduction and Background

This article describes how and why transportation safety professionals manage data quality. It starts by defining the domain of transportation safety data (also known as traffic records) and presents the guiding philosophies and techniques for managing the core datasets. This article ends with a discussion of why data quality management should be considered a formal process that goes beyond measurement to include actions designed to improve data quality.

Surface Transportation Safety Data

The domain of transportation safety typically refers to surface transportation—the safety of people, vehicles, and commodities on public roadways. The domain excludes other forms of transportation (air, rail, water, and pipelines) that have their own data standards. The list of datasets used in transportation safety varies substantially by country. In North America, Canada, Europe, Australia, and parts of Asia, South America, and Africa, the list of available data includes six core system groups: crash, roadway, driver, vehicle, citation and court records, and injury surveillance data ([National Highway Traffic Safety Administration, 2011](#)). Every country has access to a subset of the following datasets:

- **Crash data:** Records of crash events including information on the locations, people, and vehicles involved, and multiple contributing factors. These records may come from law enforcement officers and/or from the involved parties (operator reports). The formal law enforcement reports may be limited to public roadways—crashes on private roads might result in a different report type and might not be included in traffic safety analyses. Insurance companies also keep records of crashes and associated costs, but this information is seldom accessible for analysis outside of the companies' actuaries or industry-based research groups.
- **Roadway data:** There are several relevant roadway data sources. The most important, for safety analysis, are the roadway inventory data (a list of attributes for each defined location) and the traffic volume data (counts of traffic at specific locations). Other relevant roadway data include the spatial definitions of locations (e.g., the start and end points of routes, segments, intersections, etc.), asset management data (inventories of the location and condition of signs, markings, roadside appurtenances, etc.), intersection inventory data (a listing of intersections and the features specific to places where two or more roadways meet), structures data (e.g., bridges, tunnels, overpasses, sign gantries, etc.), and more.
- **Driver data:** Records of each driver's licensing, training, and history of convictions and license sanctions. Driver history data relies on court records and initial citations if there is no court adjudication (e.g., for minor violations in some jurisdictions). Training data is often lacking except for first-time licensees and special endorsements (e.g., motorcycle or commercial vehicle) where completion of training may be recorded.
- **Vehicle data:** Records of vehicle titling and registration along with coded descriptions of the vehicle's type, features, and date and place of manufacture. In some places, the vehicle data may also include indications of the vehicle's condition and mileage.
- **Citation and adjudication data:** Records of original violations issued by law enforcement officers and (if any) the court process outcomes for each violation. If citations are disposed without a court process (i.e., fines for moving violations are payable to the licensing authority directly), the record of original citation and payment may complete the record. These records form the basis for the driver history records referenced earlier in the list. Court-imposed license sanctions, training, and treatment requirements are also recorded in this data source and are, typically, transferred to the driver licensing authority as well.

- **Injury surveillance data:** There are several relevant data sources describing injuries, treatments, and outcomes for crash-involved persons. Some of these databases are available publicly (in redacted form). The first dataset describes emergency medical services provided at the scene as well as any transportation to a medical facility for treatment. If the injured person is treated in an emergency department, records of their treatment and diagnostic codes describing the injury will be recorded. The same visit may result in a record of the injuries and treatments in a trauma registry, spinal cord injury registry, or traumatic brain injury registry. For persons admitted to a hospital, the hospital discharge record will contain a record of treatments, diagnoses, outcomes/prognosis, and, in some systems, the billing records for treatments. Physical and occupational therapy centers and long-term care facilities may also keep records on those persons treated in their facilities. Finally, for those who died as a result of a motor vehicle crash, coroner's reports and death certificate data record the causes and injuries sustained as well as the date of the original event and the date of death—for motor vehicle crash-related deaths this source may be the only official record of a relationship between the event and the cause of death if the person survived the crash for a long period. Efforts to combine injury surveillance and crash data are now common throughout the world. In the United States, the original Crash Outcomes Data Evaluation System (CODES) is no longer funded by the federal government, but the project continues in several states and under different names and methodologies. Sweden has the Swedish Traffic Accident Data Acquisition (STRADA) program that similarly links crash and injury data to provide a more robust dataset for analyzing crash-related injuries.

Data Quality Principles

Data Quality Attributes

Data quality is a quantifiable aspect of data. The list of data quality attributes includes the following four core items:

- **Timeliness:** Timeliness measures the interval between a recordable event and the appearance of the data in a system ready to be used for analysis and decision-making. Depending on the dataset and the needs of managers and users, timeliness can be measured for each step in a sequence; for example, we might measure the time from a crash to submission of a crash report separately from the time from submission to posting on the database.
- **Accuracy, precision, and resolution:** These are often described jointly as accuracy—a term that describes how close the match is between the recorded data and the ground truth of whatever is being measured. In spatial data, the terms accuracy, precision, and resolution take on more specific meanings. Accuracy is the difference between the actual location and the measured location. Precision is the difference between multiple measures of a specific location (how close the measurements are to one another even if their average is inaccurate). Resolution is the variability inherent in a spatial measurement based on the capability of the measurement method or tool (each estimated location is expressed $\pm$ a specific tolerance).
- **Completeness:** Completeness measures what portion of the expected data record or full data file is complete. For example, we may wish to know the width of every roadway segment, and the completeness measure would tell us what percentage of roadways are lacking pavement width information.
- **Uniformity:** Uniformity measures how well data collection adheres to the established data requirements or agrees with any established guidance.

There are many other measurable data quality attributes. Different sources list integrity, validity, reliability, accessibility, and integration ([Australian Bureau of Statistics, 2015](#); [ECCMA, 2019](#); [Statistics Canada, 2019](#)). This longer list does present some concerns for the ability to accurately measure the attributes—much of it would require a subjective judgments by selected users. Some of these, particularly accessibility and integration, are not directly related to how the data are collected or stored, but they can have importance for users and managers. In general, it is a good idea to use a formal data governance process as a way to determine which data quality attributes are most important, and how best to measure those attributes.

Data Standards, Data Governance, and Formal Data Quality Management

Data quality management is closely tied to the concepts of data standards—including the quality requirements for specific data elements—and data governance—the processes by which all data management, not just data quality management, is achieved. A data standard provides data collectors, managers, and users with requirements the data must meet in order to be accepted into the official government database. A data standard is anything that defines the inclusion and exclusion cases for a data element, the method of collection (an operational definition), and the measurable data quality levels that must be achieved. Data governance is a formal process for establishing and enforcing data standards. It typically involves executive-level decision-makers in setting the documentation and policy requirements for every data system and a practitioner-level data governance group responsible for implementing and enforcing those requirements.

Statistical Methods of Data Quality Control

Statistical methods of data quality control are numerous and varied; however, some common features of the methods are worth exploring here. As the name implies, these methods use statistical modeling as a way to measure data quality and, importantly, set

reasonable expected values for those measurements. Using statistical methods can help agencies save time and effort by highlighting those data quality measurement results that fall outside the expected range and thus would be worth spending time and resources to address. Statistical methods also allow for a refinement in data management by calculating a data quality score for each record in a database. This score reflects how well the particular record (the collection of all data elements within the report of a single location or event) meets the established data quality standards. Examples of these two concepts follow.

Establishing Statistically Valid Expectations

Data quality measurements, and associated goals, are properly considered as a mean (or, less frequently, a median or modal) value rather than a specific point value. The true value of the measurements should fall, predictably, in a distribution around that estimate of the central value. Statistical methods of quality control set an expected range around the mean value so that data managers can ignore changes that fall within the allowed range and act whenever the obtained value(s) fall outside the allowed range. One common technique is to establish a criterion range such as $\pm$ two standard deviations from the mean. That would coincide with an expectation that data managers would only research and respond to obtained values of the data quality performance measures that are so extreme as to be expected by chance only 5% of the time. This type of criterion can avoid wasted effort responding to random fluctuations that just happen to appear worrisome from the direction of movement in the raw numbers alone. Of course, the criterion range can be adjusted to suit the needs of the data managers and key users.

Calculating Data Quality Scores for Each Record

Within the traffic records datasets, records about an event, person, or location contain multiple data elements. Each element can be weighted for importance to decision-making, and each element can have one or more data quality measurements associated with it as part of data checking and validation. A record-level data quality score is a composite of all the quality scores for the data elements in a record, weighted by the importance of each data element. This composite quality score is then appended to the record as a new data element. It can be used by data managers and analysts to judge the overall quality of the entire dataset by taking the average quality rating of all records. It can also be used to filter the database when analysts may wish to use only those records that meet a minimum quality level. If data managers establish a minimum quality level, those records that fail to meet criterion could be rejected and returned to the data collectors for correction. It is also possible to provide different quality scores for different users and uses. For example, practitioners responsible for driver sanctions might weight data elements in a crash and citation database differently to how practitioners responsible for highway engineering would weight the same data elements. Thus, it is possible to create multiple quality scores, or business-need-specific component scores, to meet the needs of different data users.

Formal Data Quality Management Processes

Data standards and data governance are part of a formal data quality management process. Agencies may use other means of managing data; however, the best practice involves the following:

- System documentation including a complete data dictionary defining each data element and describing the necessary metadata and validation rules for each data element.
- A data governance committee that develops, communicates, and enforces data standards (including data quality standards).
- Validation rules (also known as edit checks) to verify that each data element in a submitted record is of the proper type, size, value range, and format, and that it meets the established rules for logical agreement with other data elements.
- Data quality measurements that quantify (at a minimum) the timeliness, accuracy, completeness, and uniformity levels achieved in the data. The selection of data quality attributes and measurements should meet the needs of users and data managers.
- Numeric goals for each data quality measurement so that actual performance can be compared to the desired levels of quality.
- Analytic reviews of database contents to check for unexpected changes period to period, in proportions of specific codes used based on prior years' data and trends, and for differences among reporting jurisdictions. This may be combined with statistical methods of measurement.
- Feedback and correction mechanisms that inform data collectors of errors and require timely corrections by the original data source (where possible).
- Data errors and data change logging to track the frequency of each type of error in each data element, and to log the original and final data values in each field, along with who made the change and when the change was made. Systems that allow filtering by the type and source of the change allow for flexibility in meeting different users' needs.
- Linking error reports and change logs to communications content provided to data collectors. This may include changes to data collection instruction manuals, as well as help files embedded in data collection software, training, and special communications.
- Reporting data quality measurements at a level of detail that can identify the need for improvement for individual data collection sources as well as system-wide summaries.
- Including data quality improvement in major plans by the custodial agencies responsible for each database. The planning efforts should be informed by the quantitative data quality measurements and goals for data quality should be addressed in the various plans as well. In particular, there should be a comprehensive strategic plan for traffic records improvement and that plan should be referenced when related plans (such as highway safety, injury surveillance, and others) are created.

Summary and Benefits of Formal Data Quality Management

Data quality management is a process that extends beyond merely measuring data quality. It is closely related to data governance. Agencies with mature, formal data governance practices will also meet the definition of formal data quality management described here. Likewise, formal data quality management involves many of the same processes that an agency would put into practice if they implement formal data governance. Doing both is the best practice defined here.

Data quality management is not without costs. Staff must be trained in and devote time to quality assessment and improvement efforts. Rejecting data after it is collected because it does not meet the enforced standards means that there may be costs associated with getting the data up to the required quality levels. Over time, and with practice and training, the cost of maintaining data quality should level off and perhaps even drop as ways are found to automate data validation before it is submitted. The value of high-quality data must be worth the initial (higher) costs and the long-term costs to maintain the desired quality levels.

It can be difficult to estimate the value of data. It is possible to, theoretically at least, make decisions using methods that do not use data and compare the outcomes to decisions made when the data are available and of sufficiently high quality. As a thought experiment, one would expect that data-driven decisions will result in fewer costly errors and less waste—for example, by directing resources only to locations and problems that are *real* and *treatable*. In reality, however, the comparison is between making decisions with data of one quality level versus making decisions with data of a higher quality level. Some of the obvious benefits are subjective or intangible: decision-makers feel more confident using recent and complete data; more accurate data are judged as more reliable. Efforts to quantifiably prove the benefits of better data, however, are difficult to find. We do know the following:

- Advanced decision-making methods, such as those described in the *Highway Safety Manual*, require more complete and often more accurate data that many departments have maintained prior to implementing those advanced methods. Thus, poor-quality data can inhibit use of the best practice analytic methods and tools.
- When an agency decides to integrate across multiple core datasets (such as CODES projects in the United States and STRADA in Sweden), it is common for the integration effort to fail due to poor data quality in one or more of the source files. Cleaning up the errors increases the number and quality of records that are added to the new, merged data resource. The merged datasets support new insights and new analyses that were not available to decision-makers before the data integration effort.
- Poor-quality data tend to lose users over time, whereas high-quality data gain users. The evidence for this conclusion comes, especially, from years of experience helping agencies prioritize data improvement projects. Priorities are based on business needs for the information, and ultimately determine which data systems get funding and resources. If a system loses users because of poor quality, that system will get less support from key users. Decision-makers will simply look elsewhere for the information they need.

In summary, formal data quality management is the way to gain users, promote data integration, and provide the best possible support for advanced analysis. Decision-makers are the natural allies of data collectors and data managers in making decisions about where to put efforts into improving data quality. Ultimately, poor data quality can lead to costly mistakes, but more importantly high data quality can better support the best practices in decision-making.

Introduction

School buses are one of the most common modes of transportation for millions of students in the United States, Canada, Australia, and some countries in Europe and Asia. The prevalence of school bus transportation is dependent on several factors including the availability of different modes of transportation such as public transportation and social norms such as parents driving their children to school. Other factors such as the climate conditions and economic status also have a significant impact on the popularity of school buses. For instance, school transportation by private drivers is common in countries such as Kuwait and Saudi Arabia. In other countries, school bus transportation is primarily used only by private schools, and the availability of bicycle lanes leads to more students transporting themselves to school. The American School Bus Council estimates that over half the students who attend school in the United States (26 million) use school buses as the primary mode of transportation to and from school (McCray and Brewer, 2005). Taking into consideration the number of accidents and fatalities per mile driven, school buses are considered to be safer than any other mode of transportation for getting to and from school. The National Highway Traffic Safety Administration (NHTSA) estimates that students are 70 times more likely to make it to school safely traveling in a school bus compared to students traveling in a car.

School bus safety is an essential component of the pupil transportation system that primarily serves as a means of transportation between a child's home and school. As shown in Fig. 1, school bus transportation safety can be broken down into two levels. The role of the school bus transportation system starts from the point where a student leaves their home to the point of arrival at a school and vice versa. The safety concerns at each of these levels as outlined in Fig. 1 are controlled by traffic laws pertaining to school buses, Federal Motor Vehicle Safety Standards (FMVSS), and engineering controls such as rollover protection, fire protection, and emergency exits.

School buses are categorized to be one of the following types: Types A, B, C, or D dependent on their gross vehicle weight rating (GVWR), engine location, and passenger capacity. Types A and B school buses are usually smaller than Types C and D school buses and are either van conversions or constructed from the chassis of a van or a truck. Types C and D school buses are the most common type of school bus. The main noticeable difference between Types C and D school buses is the location of the entrance door and location of the engine. Type C school buses have the entrance door located behind the front wheels, whereas a Type D school bus door is located ahead of the front wheel. The front end of Type C school buses has a hood, whereas Type D school buses have a flat front face similar to commuter buses. The maximum seating capacity of Type D school buses can be up to 90 passengers, but these buses often transport 60–70 passengers comfortably. This paper provides an overview of school bus safety standards and design guidelines in addition to some of the research that is aimed to improve the safety of one of the safest modes of transportation.

School Bus Loading Zone

The American School Bus Council estimates that nearly two-thirds of fatalities involving school buses actually occur outside the school bus, whereas one-third of school bus-related fatalities occur inside the school bus. Factors such as environmental conditions and road traffic can have a significant impact on school bus passenger visibility when entering and exiting a school bus. Distraction from texting and use of electronic devices by other vehicle drivers are also a prevalent contributor to the increase in school bus stop-related fatalities and other vehicle contact with school bus passengers. Younger children especially in kindergarten through second grade are more susceptible to these types of accidents due to their small physical size and lower cognitive abilities to assess road hazards. Stop-arm extensions along with flashing red lights on school buses are the most common devices used to alert other drivers on the road of the presence of children near the loading zone of a school bus. Latest technology such as stop-arm cameras are also

Figure 1 Primary components of school bus safety.

being used in some states to obtain license plate information of vehicles that do not abide with school bus stop laws. Each state has slightly different laws regarding stopping and passing around school buses. In general, all states require that vehicles traveling on the same road as a school bus, regardless of travel direction, to come to a complete stop when stop-arms are extended or red lights are flashing on a school bus.

School Bus Safety Standards

Motorized school buses used to transport children can be dated to the 1900s when vehicles were first used to transport groups of children between home and school. Columbia University's Teachers College established the first school bus safety standards in 1939 (NASDPTS, 2000). It was not until 1977 that the FMVSS (49 CFR Part 571) for modern school bus design requirements were promulgated (NHTSA, 2011). Currently, school buses are the most regulated mode of surface transportation. Some of the prominent school bus safety standards are outlined later.

Stop-arms used to protect children entering and exiting a school bus are regulated by FMVSS No. 131. The standard regulates the design of the stop sign including its shape, color, and reflectivity properties.

Emergency exits on school buses are regulated by FMVSS No. 217—Bus Emergency Exits and Window Retention and Release. This standard provides detailed guidelines on the following:

1. Number and location of emergency exits required on school buses.
2. Requirements to open a school bus emergency exit, including the force requirements to operate latching mechanics.
3. Size requirements of emergency exits.
4. Testing procedures to test for compliance of emergency exits.

The structural integrity of the school bus is primarily regulated by FMVSS Nos. 220 and 221. These standards protect school bus passengers in accidents resulting from rollover collisions and other impact collisions. FMVSS No. 222 provides the standards for school bus seating and crash protection controls that include maximum passenger capacity and passenger protection requirements in the event of a collision. According to the standard, maximum seating capacity of school buses can be calculated given by dividing the width of a school bus bench in millimeters by 380, and multiplying the rounded whole number by the number of benches on a school bus.

School Bus Emergency Exits

The number and location of emergency exits required on a school bus is dependent on the type of school bus, passenger capacity, and the location of the engine. School buses with a maximum seating capacity of up to 57 passengers are not required to have emergency exits. However, depending on the maximum seating capacity of larger school buses, they are required to have a combination of emergency exits that include roof hatches, sidewall emergency windows, and emergency exit doors. The usability and effectiveness of emergency exits are highly dependent on the orientation of a school bus after an accident. For instance, roof hatches are ideal if the school bus is rolled over on either its left or right side; however, they provide little to no utility if the school bus was in an upright orientation or rolled over on its roof. Similarly, emergency exit windows and side doors are mainly used in evacuations where a school bus is in an upright orientation as it would be difficult to reach these exits if a school bus is rolled over to either its left or right side. For these reasons, school buses typically have multiple exits to allow for egress in multiple scenarios.

While school buses are the safest mode of transportation, further improvements can be made to provide a greater level of protection for its occupants. Limited research has been conducted to evaluate the effectiveness of safety devices such as emergency exits. With children being the primary occupants of a school bus, the design of safety devices must take into consideration the limited physical and cognitive capabilities of the most vulnerable population riding on school buses. Research studies conducted by Abulhassan et al. (2016, 2018a, b) have identified discrepancies between current designs of roof hatches and rear emergency door to the physical and cognitive capabilities of young children. The size of young children is of primary concern when evaluating the effectiveness of emergency exits. For instance, as shown in Fig. 2, the significant difference between the size of an average-sized adult

Figure 2 Illustration of a rolled-over school bus (Abulhassan et al., 2018a) (permission obtained from Elsevier RightsLink on January 28, 2019).

and an average-sized child hinders the usability of emergency exits, as some children may not be able to operate or reach these exits. Furthermore, research on the effectiveness of school bus emergency exits suggests that young children lack the physical and cognitive capabilities to meet the operating requirements of school bus emergency exits as set by FMVSS No. 217.

School bus evacuation time is an important safety measure that needs to be considered in scenarios where immediate evacuation is required such as an onboard fire. The size of emergency exits plays an important role in determining the flow rate or the number of passengers that can evacuate through the exit per minute. As the prevalence of higher obesity rates among children has increased over the last 20 years, it is crucial to evaluate the minimum sizes of emergency exits to determine if they provide an adequate level of utility in the event of an emergency.

School Bus Seat Belts

Currently in the United States, only school buses weighing less than 10,000 pounds are required to have seat belts. The increase of accidents resulting in child fatalities such as the school bus crash in Chattanooga, TN, on November 6, 2016 which resulted in the death of six children and the collision of a school bus with a dump truck in New Jersey on May 17, 2018 has led to eight states (Arkansas, California, Florida, Louisiana, Nevada, New Jersey, New York, and Texas) to require school buses with a GVWR of greater than 10,000 pounds to have seat belts. Each of the eight states has approached seat belt laws to various extents. Some states require only new buses to have seat belts, while others require seat belts on all school buses, but leave it up to the local jurisdiction to enforce wearing seat belts. Seat belts voluntarily fitted on school buses must still meet performance standards for lap/shoulder belts as outlined in FMVSS Nos. 222 and 209. Some of the seat belt performance standards include the following:

1. Seat belts ability to withstand forces in the event of a crash.
2. Buckle design including the size of the buckle and maximum push force to disengage the latching mechanism in a seat belt buckle.

School buses with a GVWR greater than 10,000 pounds use a process known as “compartmentalization” where the school bus seats are designed to act as a compartment for occupants in the event of a collision. Compartmentalization is shown to be effective in the event of a front- or rear-end collision; however, it provides little to no protection in the event of a side collision or a school bus rollover. While seat belts can provide a greater level of protection for passengers, there are some unique challenges for implementing seat belts on school buses. Enforcing seat belt usage can present a challenge due to the young age of school bus passengers. The only adult on most school bus routes is the school bus driver, and it would be time consuming for the school bus driver to ensure proper seat belt usage every time a passenger enters the school bus. Strategies such as additional training of young children may be required to properly use seat belts.

School Bus Security Concerns

School bus passenger safety from kidnapping, hijacking, and other criminal activity is an emerging concern in the wake of active school shootings and school bus kidnappings. School buses transporting young children are particularly vulnerable to these types of events due to the lack of physical measures that would prevent illicit access. The National Center for Missing and Exploited Children reports that 38% of attempted abductions occur while students are being transported to and from school in school buses and other modes of transportation including walking (Trump, 2017). The 2013 kidnapping of a 5-year-old child from a school bus after killing the school bus driver in Midland City, AL, has led to increased security measures to prevent unauthorized entry on school buses. As a result of this tragic event, the State of Alabama signed into law the Charles “Chuck” Poland Jr. Act, which makes unauthorized school bus entry and trespassing a Class A misdemeanor. Other states also have similar laws regarding unauthorized school bus entry. The

limited adult authority on school buses has led to increased training of school bus drivers to dealing with school bus security concerns, including identifying questionable bags and other items brought onboard, and diffusing altercations on board a school bus. Controls such as surveillance camera and GPS location systems are also widely used by many school districts to assist in improving security concerns onboard school buses.

Closing Remarks

A multidisciplinary approach is required to undertake safety concerns regarding the unique challenges of transporting vulnerable populations with limited capabilities compared to adults. Even though school buses are among the safest mode of transportation, continued development in the standards and design of these systems can further improve overall safety. Emerging safety and security concerns also need to be addressed to ensure an adequate level of protection for the millions of children that ride on school buses.

Introduction

School campus traffic circulation is a multidimensional issue that should be addressed on many levels. There are different educational stages, transportation modes, geographical regions, external and internal traffic, and so on. Moreover, there are different impacts, such as on road safety, congestion, air and noise pollution, greenhouse gas emissions, unhealthy mobility habits, etc. All these dimensions are intertwined and increase the complexity of addressing the issue.

First of all, there are many educational stages—apart from preschool and tertiary education, there are primary and secondary schools (in 2-stage systems) or elementary, middle, and high schools (in 3-stage systems). Many transportation modes are used for school commuting, for example, school buses, private cars, public transport, motorcycles, scooters, bicycles, on foot, etc. There are many differences per geographical region; the most studied ones being in the United States and Europe. External traffic is much more significant in pretertiary education, whereas in the case of tertiary education, where students are adults and campuses are usually much larger, internal traffic circulation is usually more important. This is the reason that these two different cases of school traffic circulation will be examined separately—(1) pretertiary school campus traffic circulation, focusing on external traffic circulation and (2) tertiary college and university campus circulation, focusing on internal traffic circulation.

Pretertiary School Campus Traffic Circulation

Going to and from school is a daily trip that millions of children undertake in the United States, Europe, and the rest of the world. Although many children walk or cycle to and from school, the major modes of transport for school commuting in most industrialized countries are school buses and cars (Anund et al., 2011). In low-income countries, walking may be the most common mode. In most cases, the elementary school population and work hours are smaller compared to middle and high schools. Therefore, middle and high schools have more complex traffic problems, such as teen drivers and, in many cases, after-school activities (Tsai et al., 2004).

Private Car

Although the main mode of transport for school commuting in the United States remains the school bus, it has become common that parents drive their children to elementary school through high school. Additionally, in the United States, where in most states it is allowed to drive from the age of 16 years or even earlier, many adolescent students drive to and from school with their own cars.

More specifically, in a hypothetical diagram of automobile use for school commuting a U-shape would be observed—the use of automobile is increased in elementary and high school and decreased in middle school, whereas the opposite is true for school buses. This is probably due to the fact that in elementary school parents prefer to drive their children to school, because they think that it is safer than the school bus, and in high school adolescent students prefer to driver to school rather than taking the school bus, probably as a sign of adulthood (Kelly and Fu, 2014).

School-campus traffic congestion is a big problem for urban areas and a source of frustration on a daily basis. This kind of congestion is short lived, usually most situations do not last more than 15 minutes, but the potential of pedestrian-to-vehicle and vehicle-to-vehicle conflicts is significant. Obviously, there are serious safety issues while mixing automobiles with walking and biking children and buses bringing children to school (Tsai et al., 2004).

In order to improve road safety around school campuses, and according to the legislative framework of each state or country, several measures can be taken, such as (1) speed zones, usually around 15–25 mh^{-1} ($\sim 25\text{--}40 \text{ kmh}^{-1}$); (2) use of traffic control devices; (3) routing and traffic layouts that separate vehicle and pedestrian conflicts; (4) use of alternative modes, such as bicycles, carpooling, and on foot; (5) better information provision with Variable Message Signs (VMS), marked crossings, flashers, etc.; (6) establishing positive interaction with stakeholders, such as parents, transport engineers, teachers, municipal and local authorities, etc. (Institute of Transportation Engineers, 1998).

Carpooling

One way to reduce school campus traffic congestion is carpooling. Carpooling can be combined both with parent driven private car drop-offs and pick-ups and with student driven private car commuting. Nevertheless, queuing and congestion problems around school campuses are created that have to be faced.

In a carpool operation, vehicle–passenger match is the single most prominent procedure. The objective is to minimize the time vehicles spend in the loading area. Ideally, students should be ready to board as soon as the vehicle arrives at the loading bay. For this to happen, the correct students should be notified in time and the vehicle must also be referenced to the respective students. This information is usually communicated through school staff members. Moreover, many schools have staff members, or upper-level students, as safety assistants. These assistants open vehicle doors, assist students' boarding, and then close vehicle doors. This procedure helps to significantly decrease the pick-up time. Other measures, such as enforcement, restrictions, and queue lane management are also used to keep queue length under control and prevent road accidents (Tsai et al., 2004).

Other recommendations regarding school campus traffic congestion may include the following (1) parents should be discouraged arriving before the afternoon school bell time, in order not to sit and idle in the carpool lane; (2) the actual loading and unloading time of students should take less than 10 sveh^{-1} and the whole process of a single vehicle entering and exiting the loading area should be completed in less than 45 s; (3) loading bays should be clearly identified; (4) schools should deploy a passenger identification system assisted with school staff members; (5) parent drivers should be guided and have limited options and restricted access to prevent vehicle-to-vehicle and, especially, vehicle-to-pedestrian conflicts; (6) schools with large walker and cyclist populations should separate them from carpooling traffic, releasing walkers and cyclists first; (7) schools should also consider implementing walking and cycling programs as a means to mitigate carpool traffic; and (8) if necessary, schools should consider implementing double queuing lane (Tsai et al., 2004).

In any case, carpooling is preferable to simple parent driven private car drop-offs and pick-ups, and student driven private car commuting, and it should be encouraged in order to reduce the total number of cars needed to serve the same number of trips. Indeed, studies have shown that carpooling can reduce traffic congestion by half, having a major positive impact on road safety and the environment.

Active Mobility (Walking and Cycling)

One of the countries that has a strong tradition of children going themselves to school, without being accompanied by parents, is Sweden. Back in 1981, 94% of all children ages 6 to 17 years walked or rode their bikes to school by themselves or with friends. Nationwide surveys show that percentage had dropped to 77% by 2000, 67% by 2003, 47% by 2009, and 45% by 2014. In 2014, an additional 34% used public transportation (or in some areas before age 8, or where public transportation is nonexistent, taxi, or buses dedicated to school transport), so only 18% were taken to school by automobiles and no one in Sweden would drive themselves by car since the license age is 18 years. The percentage that walk or ride bicycles vary between rural and urban areas and with the size of a city and with the distance to school. High schools are often located so far away that walking is not practical (Björklid and Gummesson, 2013).

Although over the last three decades the proportion of children walking to school has declined significantly, not only in Sweden but also in other European and western countries, with accompanying evidence of a sharp increase in driving children to school, lately there is a trend in Europe to prohibit car drop-offs in school campuses altogether! Some schools in Edinburgh have prohibited car drop-offs, the London neighborhood of Hackney has shut down the roads outside some schools, as has Vienna, Austria, where cars are banned from the roads leading up to a school between 7:45 and 8:15 a.m., in order to make more space for safer and cleaner modes of transport, such as bicycles and walking. Moreover, it seems that this is only the beginning as many cities are expected to follow, in the general frame of promotion of sustainable urban mobility in Europe (Schmitt, 2018).

When people walk or bike to school, the creation of woonerven zones/shared spaces around school campuses should also be considered. Studies show that although there might be some increase in traffic accidents, though with minor damages, at the

Figure 1 Bike to school day, Gastineau Elementary School, Juneau, AK. Source: Alaska Department of Transportation & Public Facilities, 2015.

beginning of their application, mid and long-term road safety increases, as users understand how they should behave and drive in a woonerf zone. Nevertheless, there should be no through traffic in a woonerf zone and, therefore, no car drop-offs should be allowed, or these should take place outside of them.

Woonerven zones, shared spaces, bicycle tracks, sidewalks, and every kind of urban regeneration that promotes active mobility (i. e., walking and cycling) should be promoted as much as possible (**Fig. 1**). Although there are road safety considerations, active mobility is necessary for students in order to reduce obesity and promote a healthy lifestyle. Child obesity has become a real problem in the developed world, especially in the United States, and the same goes for unhealthy/sedentary lifestyles (e.g., time spend on watching television and streaming video, on social media and Internet surfing, playing video games, etc.). This is one of the reasons that new policies that promote active mobility in the general frame of urban sustainable mobility are introduced, especially in the European Union (EU), expressed through Green and White Papers.

It should be noted that it is not enough that the area in close vicinity of the school is designed as a safe woonerf zone; the entire walking distance should be safe. This means that elementary schools should be located so that children do not have to cross arterials on their way to the school. Moreover, all street crossings should occur in low-speed environments. As pointed out in the article Bicycle Collision Avoidance Systems of this Encyclopedia, [Johansson and Leden \(2010\)](#) concluded that pre-school children should not encounter any cars in their play areas or where they walk; and where children ages 7–12 years are crossing a street, by bicycle or on foot, the actual vehicle speeds should be below $15\text{--}20\text{ kmh}^{-1}$, especially if they are walking unaccompanied by an adult.

Apart from the perceived risk, from traffic as well as risk of assault, there are also objective reasons that active mobility cannot fully replace motorized mobility for school commuting. Several studies show that the distance to travel is the most significant on-off determinant of mode choice. Two (2) km is a guiding “splitting line,” or threshold, between the active modes of mobility and using transit or other motorized modes. Above 2 km, students rarely walk to school and this threshold offers an evidence-based recommendation for specific school bus services or other motorized approaches. Below 2 km, a “walking school bus” can serve as a functional substitute to private car drop-offs, for certain areas given the student densities and school locations ([Kelly and Fu, 2014](#)).

Walking School Bus

“Walking school bus” is an interesting concept (**Fig. 2**). Two adults, a “driver” that leads and a “conductor” that follows, walk students to school along a set route, in much the same way a school bus would drive students to school ([Moening et al., 2016](#)). Walking school buses, like traditional buses, have a fixed route with designated “bus stops” and “pick up times.” The benefits of walking school buses can be summarized as follows: they (1) encourage physical activity by teaching the skills to walk safely, how to identify safe routes, and the benefits of walking; (2) raise awareness of a community’s walkability and also where improvements can be made; (3) raise environmental concern; (4) reduce crime and take back neighborhoods for walkers; and (5) reduce traffic congestion, pollution, and speed near schools ([Campos, 2011](#)).

Figure 2 Walking school bus program in Hermosa Beach, CA. Credit: Beach Cities Health District. Source: *The Beach Reporter*, 2013.

School Bus

Nevertheless, for distances longer than 2 km, school buses are, and should remain, the main transport mode, in at least the United States and countries in which the main alternative is car. Despite the fact that there are exceptions, especially in safer countries like Sweden in which children up to age 10 years are expected to walk or bike no more than 2 km but at age 11–13 years that distance is extended to 3 km and above age 13 years to 4 km, and regardless of what parents believe, school bus is the safest mode of transport for children going between home and school (see the article School bus safety in this Encyclopedia).

Buses are also an effective means of reducing traffic both on roads and near schools, promoting, thus, environmental protection and road safety. There are several schemes of school bus ownership and operation: although many are owned and operated by school districts, others are controlled by third-party contractors who run them on behalf of schools (Schroth and Helfer, 2014).

It should be mentioned, though, that there is a clear difference between school buses in the United States and Europe, as well as the rest of the world. In the United States school bus vehicles and operation were evolved after a long tradition of standards' development. We should remember "the father of the yellow school bus" Frank W. Cyr and his efforts, that led to a set of 44 standards for school bus construction, which were adopted by all manufacturers. These 44 standards led to consistent interior dimensions, seating configurations, and other features that permitted new consistency in industrial production for manufacturers, leading to decreased complexity, which subsequently reduced the price per unit for purchasers (Fig. 3). The "National School Bus Glossy Yellow" was selected as the easiest color to see at both dawn and dusk and, although this was never officially adopted by the federal government of the United States, it has become the de facto choice for school buses both in the United States and the rest of the world. Moreover, regarding the accessibility of People with Disability (PwD), small school buses are often equipped with special devices to assist PwD, such as automated lifts (Schroth and Helfer, 2014).

The system of school transport in the United States differs from the school transport system in Europe and the rest of the world. In the United States, the school bus itself is an icon and functions as a "mobile traffic STOP sign," as it requires other vehicles to stop and not overtake it while children are boarding or alighting. In the United States, on a daily basis, more than 22 million children are transported to and from school in specially designed school buses. School bus is the safest transportation mode available for students to go to school in the United States; a student on the way to school is eight times more likely to be injured while traveling to and from school in a vehicle other than a school bus. Nevertheless, illegal overtaking of school buses remains problematic as, statistically, a child is three times as likely to be killed as a pedestrian in the "loading zone" around the school bus when the school

Figure 3 Types of school buses in the United States. Source: *United States Government Accountability Office*, 2017.

bus is present than to be killed as a passenger in the school bus. An interesting fact is that, apart from the illegal overtaking vehicles, many students are hit by the actual bus they intended to ride or rode with (Anund et al., 2011).

On the contrary, many of the features of the school transport system in the United States do not apply to most EU countries and the rest of the world. Instead, it is more common in EU to have a mixed system of school transport. Some students are transported by vehicles provided for school children, but they do not have any special features or traffic rules applying to their presence on the road, such as in the case of the United States, apart from specific EU regulations related to seat belts and the display of a school bus sign. Moreover, many students in EU use public transport for school commuting. Because of this mixed system, school-related EU injury statistics are more difficult to obtain. However, findings show that: (1) the majority of the children on school transport who are fatally injured are not vehicle occupants; (2) they are in the area outside the bus on their way to or from buses; (3) boys seem to be overrepresented; and (4) the afternoon journey is particularly vulnerable. Running out behind the bus in the afternoon was a common conflict scenario, and perhaps EU should adopt the practice of school buses in the United States that function as mobile traffic STOP signs (Anund et al., 2011). Parenthetically, on the other hand, official statistics of children ages 0–17 years killed in traffic from 2004 to 2008 was lower per capita in every single EU country than in the United States and the rate in the United States was 3.35 times that of Sweden's. Furthermore, Sweden, as opposed to the United States, has drastically improved its safety in the last decade, reducing the number of children killed in traffic from an average of 30.6 actual fatalities per year in the time period 2004–08 to 12.6 in 2013–17 in spite of a growing population. In addition, it should be noted that most children that are killed in traffic are 15 or older. In Sweden, only about one child per year is killed in each of the age groups 0–2, 3–5, 6–8, 9–11, and 12–14 years so about two-thirds of all child fatalities occur among 15–17 year olds. The fact that Europe has better traffic safety for children than the United States does not mean that Europe should not invest in safer school buses. It means that the United States needs to have more children use school buses and improve the walking and bicycle environment for children, as well as having them travel less by car, since the fatality rates above include all activities, not just going to school.

School bus occupants have a good safety record all around the world. There are several regional differences though. In the United States, there are three times as many children killed around school buses compared to those killed inside a school bus. In New Zealand, Australia, the United States, and Canada most school bus incidents happen while pedestrians are alighting from the bus in the afternoon. There is a notable difference, though—in the United States and Canada the majority of student pedestrian casualties are caused by their own school bus, whereas in Australia and New Zealand the students injured after alighting were more likely to be injured by another vehicle. Probably, this reflects the different approaches in traffic education—in the United States and Canada children are encouraged to cross the road in front of their bus, whereas in the United Kingdom, Australia, and New Zealand the norm is to teach students to cross the road after their bus has left the bus stop (Anund et al., 2011).

Studies show that children do not see school commuting as a part of their school day. Therefore, children when alighting feel that they enter “play time” and the result is a sort of cognitive distraction. Another explanation for the casualties when running out behind (or in front of) the school bus could be that children cannot perform beyond their degree of maturity. The frontal lobe, which is the brain region that is essential to foresee the consequences of behavior, is one of the latest parts in the brain that is developed. Consequently, children do not have fully developed the capability to foresee a possible critical situation when alighting. This fact raises the need for effective risk assessment and management of the location of school bus stops, to ensure they are not in complex traffic environments which children are inherently unable to cope with. The consistency of these casualty patterns in several regions emphasizes the need for effective road safety education, ensuring that school commuting is regarded as an integral part of the school day and, thus, under the school's responsibility (Anund et al., 2011).

Despite all the aforementioned problems with school bus commuting, it is clear that school bus is the safest mode of transport to and from school. It is important to keep in mind that most children are injured or killed as passengers in private cars or as vulnerable road users (i.e., while on foot or cycling). Actually, data from the National Highway Traffic Safety Administration (NHTSA) indicates that a child is 50 times more likely to be killed on the way to school if traveling in an automobile driven by themselves or their friends than if they take a school bus (Schroth and Helfer, 2014)!

Motives

Here comes the need to persuade both the parents and the adolescent student drivers that school bus is the safest mode of transport for school commuting. In this attempt, the role of motives is crucial. The perceived risk plays a very important role in modal choice for school commuting. Many parents believe driving their children to school is safer than letting their children ride the school bus, despite the contrary statistics.

Studies show that for each parent who believes that “school bus is very safe” two believe that “private car is very safe,” and, of course, parents who believe that private cars are more safe are more likely to ride in an automobile for school trips, whereas students whose parents believe the school bus or non-motorized modes to be most safe are more likely to ride the school bus. Parental perception of modal safety is paramount. If there is to be systemic change resulting in modal share shifts and in decreased traffic congestion around schools, addressing parents' subjective perceptions about the relative safety of the school bus and private car is critical. Most parents believe the automobile to be a “most safe” means of transport, although injury and fatality statistics suggest otherwise. In order to shift students from private cars to school buses, this bias has to change (Rhoulac, 2005)!

Some findings indicate that, in some cases, socioeconomic status, expressed in average median household income, is usually inversely proportional to the probability that a student will be driven in a private car for school commuting (Rhoulac, 2005). Although this could be explained by the probable longer home-to-school distances of wealthy suburbs, another reason could be that, due to better education, parents of higher socioeconomic status understand that school buses are safer than private cars.

Interface Management

Another very important aspect of school commuting road safety is the management of interfaces. Most accidents occur at interfaces in space and time. Examples of interfaces in space are carpooling loading bays, bus stops, pedestrian crossings, etc. Examples of interfaces in time are cases in which pupils feel that school time has finished and play or free time begins after alighting, etc. All these interfaces should be managed accordingly and one way to address this issue is to apply the road safety “travel chain perspective,” which means that every trip from and to school involves all necessary steps from “door to door.” For example, in the case of school bus, this means that going to and waiting at the bus stop, as well as boarding and alighting, are integral parts of the trip. The concept of road safety “travel chain” is derived from the concept of “accessible travel chain” and there are research projects that promote this approach, such as SAFEWAY2SCHOOL (Anund et al., 2012). By the way, obviously commuting travel chain should be accessible for all.

Conclusion

In summary, there is a need of an integrated approach to school commuting—(1) all private car drop-offs should be shifted to carpooling or school buses; (2) gradually even carpooling drop-offs should be shifted to school buses; (3) an exception to the previous guidelines is the trips realized with active mobility modes, such as walking and cycling, which have to be promoted; (4) even in the case of distances greater than 2 km safe active mobility measures should be promoted, such as alighting students at some distance before schools in order to be forced to walk or cycle to the school in woonerven zones or safe pedestrian and bicycle tracks; and (5) all the previous measures should be taken in an integrated frame of an accessible and safe “travel chain perspective.”

Tertiary School Campus Traffic Circulation

In the case of colleges and universities, almost all students are adults and their commuting does not differ so much compared to typical commuting of employees. Aspects closer to pre-tertiary education commuting have already been covered in the previous part of this article. Obviously, in the case of tertiary school campus traffic circulation, the most important part is internal traffic, that is, the traffic circulation inside the campuses, which in most cases resemble to small villages. However, many campuses have parking lots located on the outskirts of the campus, and most serious accidents occur not in the center of campus but when students cross arterial or collector roads walking from parking lots to classrooms. So, any improvement plans need to include such streets.

There are several approaches to college and university campus traffic circulation. Most of them can be grouped in the following three categories: (1) segregated traffic, (2) no traffic (i.e., full pedestrianization), and (3) mixed traffic (i.e., woonerf zone).

Segregated Traffic

The proponents of segregated traffic in campuses usually are transportation engineers with a conventional traffic engineering approach. According to this approach, creating segregated traffic lanes for cars, bicycle tracks, pedestrian sidewalks, and, in general, segregating traffic increases road safety and creates a viable campus for every type of user. Although this approach seems to be the dream of every transport engineer, who sometimes consider campuses as playgrounds in which they can make their dream come true, it has some drawbacks. More specifically, a lot of space is needed to segregate traffic, and especially in the case of most European campuses simply there is not enough. Moreover, segregated traffic lanes for cars have as a result speeding inside campuses; remember that most drivers in campuses are novice young drivers, not to mention that half of them are men. Therefore, although the approach of segregated traffic seems to be ideal at first glance, in real life this is not always the case.

No Traffic

The opposite approach is that of no traffic at all or, else, full pedestrianization. Usually, the proponents of this approach are environmentally aware members of the academic community and, indeed, in case there are enough parking spaces around the campus or adequate public transport service, this is the best solution. There are beautiful campuses all around the world that allow no traffic at all. Given that there are solutions for PwD and the elderly (Demir-Mishchenko et al., 2010), perhaps this should be the ultimate goal of every college or university campus. To achieve such a goal, undergrounding the necessary parking facilities should be considered but parking spaces should not be so many that would generate additional trips to campus. In the case of larger campuses, maintenance traffic as well as bus traffic may be needed, but such traffic can be restricted to occur only during class times and banned during the 10 or 15 minute periods when students walk between classes.

Mixed Traffic

Nevertheless, in case there are no parking lots around the campus for park-and-walk or adequate public transport service, the pressure to allow internal traffic in campuses is very strong and, sometimes, justified. In such campuses, especially if they are located

Figure 4 Woonerf zone in Downtown Raleigh, NC. Source: *Institute for Transportation Research and Education, 2013.*

in urban areas where public space is limited, there is an ongoing battle between drivers and pedestrians. In these cases, the woonerf zone approach seems to be a feasible and viable solution, a “via media” between the proponents and opponents of private cars, compared to infeasible maximalist proposals of full pedestrianization (Nalmpantis et al., 2017; Vasileiadis and Nalmpantis, 2019). Moreover, inside a woonerf zone human interaction is not disturbed by traffic (Fig. 4).

The beauty of the true woonerf zone, as it was defined by law in the Netherlands in 1976, is that the maximum speed allowed is qualitatively defined: “Article 88b KVV: Drivers within a ‘Woonerf’ may not drive faster than at a walking pace” (Ben-Joseph, 1995). As the average walking pace is very slow, there were interpretations of that being the pace of a walking horse, that is, around 10 kmh^{-1} ($\sim 7 \text{ mh}^{-1}$), and currently even 15 kmh^{-1} ($\sim 9 \text{ mh}^{-1}$), that is close to the speed of a racewalker, is considered to be acceptable. In the United States, shared spaces typically allow an upper speed limit of only 20 mh^{-1} ($\sim 30 \text{ kmh}^{-1}$), which is the maximum theoretical running speed of human beings; according to evolutionary psychologists our psychology and physiology have evolved based around that while hunting, therefore an individual’s ability to interact and retain eye contact with other human beings diminishes rapidly at speeds greater than 30 kmh^{-1} . Obviously, it is not a coincidence that safety analysts have known for several decades that the maximum speed at which pedestrians can escape severe injury upon impact in most cases is just under 30 kmh^{-1} ; that or less should be the upper speed limit in order to have an even lower possible impact speed (as recent data from the United States show that if hit by a motor vehicle at 30 kmh^{-1} young adults and young children with the elderly have a 2% and 15% fatality rate, respectively).

Conclusion

In summary, the management of internal college or university campus traffic circulation depends on the peculiarities of every institution. Preferably, the solution of full pedestrianization should be pursued but only in case there are parking lots around the campus for park-and-walk, adequate public transport service, and provisions for PwD and the elderly. In case these conditions are not met, the second best solution is a woonerf zone.

Biography

Dr. Dimitrios Nalmpantis is a member of the Laboratory Teaching Faculty of the School of Civil Engineering of the Aristotle University of Thessaloniki (AUTH) and a member of the Adjunct Teaching Faculty of the Hellenic Open University (HOU). He holds a PhD in Transportation and Road Safety, an MA, an MBA, and an MEng. He has participated in more than 25 research projects and he has published more than 60 peer-reviewed papers in scientific journals, conferences, and edited books as chapters.

The Nature of Sexual Violence in Public Transportation

Sexual violence can be a vast array of sexual behaviors that vary from sexual harassment to sexual assault. The boundaries between these types of acts are blurred. In the literature, sexual harassment is said to be unwanted sexual attention, while sexual assault takes place when a person is threatened, coerced, or forced into a sexual act against her/his will. Cohan and Shakeshaft (1995) already in the 1990s distinguished between what they called noncontact and contact sexual violence. In the noncontact category, they identify nonverbal sexual abuse (such as exhibitionism, showing sexually explicit pictures, or making gestures) and verbal sexual abuse (such as sexual comments, jeering or taunting, and asking questions about sexual activity). In the contact category, they include sexual abuse such as touching, kissing, and rape. Fig. 1 illustrates a list of acts, which include a vast array of sexual behaviors under the denomination “sexual violence.”

Although not well understood, the risk of victimization of sexual violence is expected to vary across types of individuals (age, gender, (dis)ability, LGBTQI status, IT literacy, previous victimization, frequency of use of public transportation, length of trip, etc.), over time (rush hours, off-peak hours, days of the week, weekends, weekdays, and seasonal differences), and by different public transportation modes and settings along the trip (Gekoski et al., 2015, p. 6). Since some transit environments are often places of convergence, crime opportunities, including sexual violence, are inherent parts of the daily rhythmic flow of people passing by in these transit environments. Public transport or public transportation is the term used here to capture what North American readers often call “public transit,” “mass transit,” or “rapid transit” systems (Newton, 2014, p. 709). These systems compose forms of transport that are available to the public, charge set fares, and run on fixed routes, such as trains, buses, and trams. When safety is associated to public transportation, the journey not only involves the bus ride or the trip by train; it includes a whole journey perspective; in other words, this perspective considers safety throughout the whole trip, from door to door (Natarajan et al., 2017). For instance, safety in the environments to which an individual is exposed when walking to the bus stop, waiting for the bus to come, inside the carriage on the trip, changing transportation modes, arriving at a destination, and returning back home. In order to obtain a better understanding of risk of sexual victimization in public transportation, it is necessary to untangle the intersection between riders’ individual characteristics and the characteristics of the multiplicity of environments they are exposed to from door to door, at a particular time, and all possible times they would make such a trip.

Why Care About Sexual Violence in Public Transportation?

Firstly, sexual violence is highly gendered. Worldwide, women more often are exposed to unwanted sexual behavior than men are while in transit. This is partially because women travel by public transport more often than men do and, in some countries, they

Figure 1 Types of sexual violence in public places. *Source: Adapted from RedDot Foundation SafeCity initiative.*

constitute the so-called “transit captives,” which means they have relatively less access to nonpublic forms of transportation and are therefore overly reliant on it. For example, in Sweden, previous research has shown that women are less likely to have access to a car (Lundkvist, 1998), and tend to take more, shorter and more varied trips (trip chains) at more varied times (although they tend to travel less at night) (Kunieda and Gauthier, 2007; Ceccato, 2013, 2014b). In the United States, a study showed that 64% of the people riding Philadelphia’s subways and buses were women (Goodyear, 2015). That share is 62% in Chicago’s MTA and 60% in Washington, DC, New York, and Boston. Being a victim of sexual violence can have serious psychological and behavioral effects and may result in women and members of vulnerable groups (e.g., disabled people, LGBTQI) being too afraid to use buses or trains. If public transportation is not safe, or rather perceived not to be, the mobility of half of the population of the globe may be impaired, which directly affects individuals’ life opportunities (Junger, 1987).

Secondly, sexual violence has become more and more part of the public transportation agenda. The #MeToo! Movement has shown that sexual violence includes more than sexual harassment in the workplace, even including other unwanted types of sexual behavior that were in the past normalized by social and cultural norms in society. An example of this growing interest is a recent special issue that brought together 10 articles that characterize women’s victimization and safety in transit environments Ceccato, (2017b).

Thirdly, cities are to be planned having the UN 2030’s sustainability goals in mind (UN, 2019). If one wants to promote the use of more sustainable transportation (such as buses and trains but also walking and bicycling), personal safety must become a priority. This is particularly true for women and other vulnerable groups. Recent research shows that in order to foster transit use, personal safety has to come first and include an increasing public awareness of transportation-related environmental issues (Hsu et al., 2019). A non-neutral gender agenda for transit safety does not mean the implementation of radical solutions such as “women-only cars” or “women-only waiting rooms.” Although women-only transport may be an effective means of reducing unwanted sexual behavior on public transport, such measures are, at best, “short-term fixes” to the problem that at the end may penalize women by limiting their choices of transportation (limited supply of cars in particular time-frames). Moreover, there is an underlying assumption that these solutions may not be appropriate for countries where current gender inequalities do not result in extreme, unsafe transit conditions for women. Thus, there is an urgent need for a better understanding of the societal, economic, and institutional barriers that hamper the incorporation of women’s voices and views from vulnerable groups into transport service policies.

The People Most Affected by Sexual Violence in Transit Environments

Gender

Studies have shown that while men are more often crime victims on public transport (Morgan and Smith, 2006) women declare being more fearful than men (Dymén and Ceccato, 2012; Ceccato et al., 2013; Loukaitou-Sideris, 2016). That may most likely be because women are more exposed to sexual violence, and particularly in transit environments (Ceccato, 2013, 2014b; Ceccato and Loukaitou-Sideris, 2019; Moreira and Ceccato, 2019). In Britain, research has found that around 15% of women and girls have been subjected to unwanted sexual behavior on the London transport network, the vast majority of which goes unreported (Transport for London [TfL], 2013). A recent international survey performed among college students by Ceccato and Loukaitou-Sideris shows that victimization can reach more than half of the consulted population and gender is the most powerful predictor of sexual victimization (Fig. 2A, B). Although the sample may not be representative for the general youth population in some of the cities studied, the survey provides good indications of how sexual victimization affects those most targeted by this crime, specifically the youth

Figure 2 (A) Sexual violence victimization among university students in the transport system (on trains/buses and on the way to them, women only) in selected cities (% of respondents) and (B) sexual victimization on buses in selected cities (% of respondents). Note that samples vary from 350 to 1,200 students and that the cities differ in their public transportation system. Source: *Ceccato and Loukaitou-Sideris (2019)*.

population. In Stockholm, for instance, sexual violence on trains reaches 43% of those surveyed (62% women, 12% men) and for women only in public transportation, sexual victimization reaches 54%, but, as [Fig. 3](#) shows, it varies by type (verbal, nonverbal, or physical sexual violence) and whether the young rider is on the bus or on the train. Some of these events, such as rapes, cause a long-lasting trauma in the victims. In Stockholm municipality, reports of rape (including attempts) reached around 600 cases in 2016, about 30% of these cases happening outdoors committed by a person unknown to the victim. In a sample of 67 of these cases (all women) 2008–9, Ceccato in 2014 showed that 76% of these cases took place less than 500 meters from a bus stop and 53% of them less than 500 meters from a metro/train station ([Ceccato, 2014b](#)).

LGBTQI Status

In a study in the United States, [Lubitow et al. \(2017\)](#) found that transgender and gender nonconforming individuals often experience harassment, which undermines their access to safe public transportation. Similarly, evidence from the Global South study shows that sexual violence does differ among members of the LGBTQI community (gay women being more exposed to sexual harassment

Figure 3 The nature of sexual violence by type and public transportation mode in Stockholm, Sweden. “In the last three years, have you experienced any of the following while traveling on, heading to, or waiting for the bus (please mark all that apply)?” Sample of university students only. $N = 991$ university students in rail bound public transportation and $N = 853$ university students in buses, Stockholm, Sweden, 2018.

than cisgender women) (UOL, 2014), but the main overall message is that LGBTQI as a group composes a vulnerable target for harassment, abuse, and potential street crime in public places (Doan, 2007). The interactions of LGBTQI status with ethnicity and socioeconomic status are also reported in the current international literature.

Age and Disability

Research shows that young women are more likely to be victimized by sexual violence in public places than are older women, including in public transportation (Whitzman, 2007; Madan and Nalla, 2015). As suggested by Gray (2018), young women in particular have to do their “safety work” before leaving their homes, or commuting to college, work, and recreation. In Sweden, the 2018 national crime victims’ survey showed that the vulnerability for sexual crimes differs greatly between different age groups. The proportion is highest in the age group 20–24 years for both women and men. In this age group, 36% of women state that they were subjected to sexual offenses while for men the figure is close to 5% only. Note that in the oldest age group for both men and women (75–84 years), only 0.4% state that they were exposed to sexual victimization in that country (BRÅ, 2019). For perceived safety, other studies found that older women are more likely to be afraid of victimization in transit environments (e.g. Levine & Wachs 1986).

With age, we may face a number of disabilities (Sochor, 2015), increasing the risk for unwanted sexual violence. As Iudici and colleagues indicate, disability is associated with a higher incidence of victimization, and scholars find that women with disabilities are among those who suffer the most from sexual assault in transit environments (Iudici et al., 2017). Evidence from Sweden by Ceccato et al. (2013) indicates the geography of fear among older adults follows a distance decay from their own residence; this means that older adults become more dependent on their own familiar surroundings to feel safe, although victimization may not necessarily follow the same pattern, happening often at home (e.g., residential burglary).

Previously Victimized

The chances of one being sexually victimized in transit are positively correlated with previous victimization of sexual violence (Ceccato, 2014a; Ceccato et al., 2017; Ceccato et al., 2018). This increased risk of sexual victimization is linked to an individual’s personal profile, including lifestyle choices and/or the environmental contexts she or he is exposed to.

Ethnicity

An individual’s ethnic background (here loosely associated with one’s “race” and “ethnicity”) may also be a key factor explaining one’s experiences of sexual violence (Sommers et al. 2006). The recent study across six continents of sexual violence among college students shows evidence of how ethnicity contributes to increased risk of sexual victimization and how such risk varies by transportation mode, along the trip, and by city and country contexts. This increased risk of victimization affects one’s perceived safety and may impair daily mobility. A study in the United States by Loukaitou-Sideris showed, for instance, that nonwhite women often experience higher levels of fear than white women experience, and tend to be fearful of white men, while white women tend to fear nonwhite men, which may be the result of both racial prejudice and persistent racial hierarchies (Loukaitou-Sideris, 2004; Ceccato, 2016; Newton, 2018).

Socioeconomic Status

The #MeToo! Movement has shown that sexual violence is an issue that transcends socioeconomic status. However, being often transit captives, poorer women worldwide may be more exposed to sexual violence than any other group. Evidence about the individual impact of income and/or socioeconomic status on sexual violence is relatively rare. In the United States, for instance, research has found that low-income women were more fearful of crime, assaults in particular, in public spaces and transit environments than higher-income women because they live in high-crime and unsafe neighborhoods (Loukaitou-Sideris 2005).

Underreporting

Unwanted sexual behavior is highly underreported (Gekoski et al., 2015). It is believed that around 15% of Londoners have experienced unwanted sexual behavior on the public transport network, but 90% of those affected do not go on to report it to the police. Most people report to family and friends but are reluctant to report to security guards or go to the police. Ball and Wesson in 2017 showed that passenger density in a transit setting influences the incident seriousness and also the likelihood of reporting an event (Ball and Wesson, 2017). The reasons for not reporting varied, but often riders thought the crime was not serious, it was a “waste of time” (as they think no one would be able to catch the abuser), or they did not want to create “more problems” or be reminded of the event. The embarrassment felt by victims of sexual harassment due to cultural pressure may also result in underreporting (Gray, 2018). Yet, despite the common occurrence, the majority of cases of sexual violence go underreported, as these unwanted sexual behaviors become normalized through individuals’ actions and experiences, becoming an invisible problem (Mellgren et al., 2018). High rates of underreporting mean a lack of reliable information about sexual violence in public transportation, constituting a key barrier to its prevention (Solymosi et al., 2018).

Situational Risky Conditions for Sexual Violence

Many of us would associate a crowded bus with groping and an empty station with the necessary conditions for indecent exposure. Research shows that some sexual behaviors actually “demand a crowd” while others “require anonymity” to happen. Less known is whether and how transit environments make sexual violence possible and, in other situations, they can prevent it. The internal design of carriages and buses, the physical and social environment of transport nodes (such as stations and/or bus stops), as well as the socioeconomic and land use contexts of transport nodes impact on the levels and types of crime that happen in these transit environments (Madan and Nalla, 2015) Newton (2018). Sexual violence is no exception. Studies based on traditional environmental criminology theories that associate the characteristics of the environment (in which transportation nodes are located) to poor social control and crime (e.g., broken windows theory, spiral of decay, crime prevention through environmental design, routine activity, social disorganization theory, situational crime prevention, etc.) provide a framework for the understanding of the situational conditions of sexual violence in transit environments as illustrated later.

Selection of International Evidence

High-density environments (in particular, overcrowded carriages) are a facilitator of crimes against women—a condition that may also trigger bystanders’ interventions. In an Indian study that explored actual and witnessed victimization as well as risk perceptions of a sample of female students, Tripathi et al. (2017) showed that sexual harassment appears to be most prevalent on buses, and increases with the frequency of public transport use. More interestingly, they found these events are not widely noticed by other passengers. There is evidence in the literature that most people pretend not to witness what is happening, or they declare not being ready to intervene. Other studies have investigated which strategies are the best for women when they are sexually assaulted in buses, for instance in Lea et al. (2017). In this particular study, women’s strategy of confronting incidents by “making a scene” and “engaging the crowd” plays in their favor in the closed, shared-space setting, such as crowded buses.

In the United States, previous research shows that commercial areas near transit stops, especially liquor stores, bars, and check-cashing establishments, as well as residential environments, particularly multifamily housing, are associated with higher crime rates at transit stops as compared with office and industrial environments, and such differences may be explained by higher density in the former (Loukaitou-Sideris, 2012). In the Sao Paulo metro, in Brazil, sexual violence constitutes 12% of total reported crime—crimes that are highly underreported. Sexual violence there is linked to the characteristics of these transport nodes (the presence of employees in the station, the presence of CCTV, type of station, etc.) and the different types of criminogenic land uses and socioeconomic demographics of the neighborhoods (poor areas, located close to a parking lot) in which public transportation operates. (See the recent study by Ceccato and Paz (2017) and Moreira and Ceccato (2019). Both studies indicated concentrations of sexual violence in space and time (the busiest central stations, often during morning and afternoon rush hours) for women.)

In a series of studies on rape in Stockholm, Sweden, Ceccato and colleagues found that subway stations increase the risk of outdoor rape in an area by over 50% with 95% credible interval (Ceccato et al., 2018). Note that rapes did not happen at the stations per se but on the way to or from these transport nodes. Using another data source, they showed that rape was significantly more likely to occur at a time when women were passing by a forested area, in an interstitial area (between buildings, desolated area), or in

private transportation (taxi, other private mode) than when they were in an indoor public setting (Ceccato, V., Wiebe, D.J., Eshraghi, B., Vrotsou, K., 2017). The study also showed significant variations over weekday and weekend, as well as seasonal patterns using police recorded data. This analysis, focusing on innercity areas, showed that rape typically happens in secluded inner courts between buildings, walkways, hilly areas where visibility from the street is difficult (stairs), ditches, tunnels that link to public transportation, and small parks, including cemeteries. In the periphery, the typical locations for rape included interstitial spaces between roads and buildings, often paths or streets with poor surveillance and close to transport nodes (Ceccato, 2014a). They also showed that the situational conditions 12 hours before a rape affected the risk (odds) of the rape taking place—findings that point out the importance of adopting a whole journey approach to ensure women’s safety. Informed by a “whole journey” approach to safety that includes walking to and from bus/subway stops as well as waiting for and riding the bus or subway Natarajan and colleagues assessed young women’s experiences of sexual victimization during the commute to college in New York, United States. Their findings showed the extensive patterns of victimization during all stages of the trip to college (Natarajan et al., 2017).

The Impact of Sexual Victimization

Transit users respond to the risk of transit crime by engaging in defensive behaviors. Common precautionary measures include changing travel time/mode/route, traveling in groups, choosing other times of the day, staying home, selecting defensible positions within a carriage, standing near “safe” people (typically other women), or using objects to shield themselves. According to Kash (2019), these behaviors allow some victims to regain a sense of safety while using public transportation while others may struggle with hypervigilance, anxiety, and other responses to sexual trauma. A recent study in France (d’Arbois de Jubainville and Vanier, 2017) assessed whether and how female passengers change their routines when feeling unsafe in the transit environment in the Paris region. They suggested that women’s education, previous victimization, and declared perceived safety are consistently associated with time-based and space-based avoidance.

Public Transport, Sexual Violence, and Prevention

A wide range of interventions have been introduced through particular programs that often encompass a bundle of measures to tackle sexual violence. Common safety interventions may include design strategies (e.g., improving lighting, decreasing disruptive objects, increasing visibility, good maintenance of transport facilities, implementing real-time scheduling information), passenger separation strategies (e.g., Women-only Cars/taxis, splitting passenger flows), improvement of surveillance (e.g., CCTV, the presence of security officers, training of personnel and passengers to be alert and intervene, hotlines, implementation of emergency buttons in carriages, SMS services), targeting routes (hot spots known to have higher crime rates), raising awareness (campaigns to motivate individuals to report, organizing public workshops, actions through social media in collaboration with existing campaigns used in raising awareness about sexual violence in public spaces). There is limited evidence about the effectiveness of these interventions, in particular campaigns aiming at public education and awareness raising.

An example of a campaign in Sao Paulo showed limited incentives for sexual abuse detection, and by doing so it is neglecting victims’ needs and support. Another problem has been that campaigns of this type rely heavily on users to report these offences, but very little is suggested about the transport operators’ role after the event has already happened. Some claim that these campaigns take away the transportation company’s responsibility and move it to victims and passengers, to deal with the problem (Ceccato and Paz, 2017).

Emerging Issues and Future Debate

Assuming that sexual victimization is never justified, it is important in future research to improve our knowledge about women’s behavior (over which women are free to have total autonomy and carry out in the absence of the threat of sexual victimization) in situational contexts in which women become a target in public transportation. This is of relevance since the identification of these conditions is crucial to create opportunities for prevention. Fundamental in this process is to incorporate women’s voices and other vulnerable group’s views into public transport services and policies.

In practice, adopting a “whole journey approach” to transit safety means that we must take into account aspects of the transit journey for female passengers and other vulnerable groups that are specific: some demanding a combined attention from transportation providers, local governmental authorities (including police departments), policy-makers, and other stakeholders.

Finally, increasing the safety of passengers has, for various reasons, not been high on the agenda of transport agencies and governments, often adopting gender-neutral policies, rarely sensitive to the needs of those who are often the target of sexual violence in transit environments (Loukaitou-Sideris, 2014). A non-neutral gender policy does not need to lead to “Women-only cars” or other extreme solutions that are found in some transportation systems around the world. Aligned to the UN’s 2030 sustainability goals, a more progressive agenda in transportation policy is needed. As previous research suggests, transit agencies often have a general interest in providing adequate services to all customers, but unless a specific effort is made to ask those riders that are more often the target (of sexual violence), what they need and want and how services can be improved, suboptimal solutions persist. Solutions may

require structural changes through, for instance, recruitment of female personnel in transportation systems, often a male dominant environment (Rivera, 2007). It is expected that as more women and members of vulnerable groups are recruited to work in transport agencies in every area (from design and maintenance of transportation nodes and carriages, to customer services and bus drivers), they have a chance to reflect upon their needs and use them to transform environments and services to make everyone safer.

Biography

Vania Ceccato is a Professor at the Department of Urban Planning and Environment, School of Architecture and the Built Environment, KTH Royal Institute of Technology, Stockholm, Sweden. She coordinates the national network Safeplaces (Säkraplatser nätverk) funded by The Swedish National Crime Prevention Council (BRÅ). Ceccato is interested in the relationship between the built environment and crime and perceived safety, in particular the space–time dynamics of crime and people's routine activity. Gendered safety and the intersectionality of victimization are essential components in her research and teaching. She is the author of numerous articles and books in the area of the situational conditions of crime and fear in urban and rural environments.

Introduction

Communities are increasingly grappling with the impact motor vehicles have on road safety and quality of life due to concerns surrounding speeding, congestion, and air pollution. This can be seen in the growing number of places enacting congestion charges, lower emission zones, and so on. There is also increasing interest in redesigning cities to minimize driving and keep vulnerable road users safer. Fatality rates for motor vehicle occupants has been decreasing for many years but the fatality rates of vulnerable users such as bicycle riders and pedestrians continues to increase throughout most of the world. There are many possible reasons for this including distracted driving, lax speed enforcement, and a growing number of SUVs on the road with their higher profiles. Other reasons for creating shared space areas include climate change and air pollution, the obesity epidemic, increasing traffic congestion, and vehicular injuries to pedestrians and bicycle riders. The desire for safer streets has spawned multiple movements including Livable Streets, Complete Streets, Safe Routes to School, and Shared Space (also known as Naked Streets or Curbless Streets).

This chapter discusses shared space as a concept and design solution. The chapter defines the concept and its foundations and explores the history of the movement. Then the chapter will delve into the features of shared space designs and provide a few examples of built projects. Because shared space is a controversial technique, this chapter will also touch on some of the current debates.

What is Shared Space?

The overarching idea behind the shared space concept is that the streets are for people and that no single transportation mode should dominate public space and/or roadways. This technique is used to modify road straightaway and intersections into more accessible spaces for all people including pedestrians and cyclists and users of all ages and abilities. Therefore, shared space can be best considered both a form of urban design as well as a form of traffic calming.

The primary goal of a shared space project is the reduction of motor vehicle speeds in order to improve the safety of pedestrians, bicyclists, and motorists without unduly interfering with traffic flow. The language of design and uncertainty are used to communicate to all users that no one mode has priority over any other. The appeal of shared space projects has become increasingly popular worldwide over the last several years. For instance, the United Kingdom has at least 20-shared space projects on the ground as of 2018. There are also several in the United States in cities ranging from Philadelphia to Salt Lake City as well as in Switzerland and Sweden. **Fig. 1** shows an example of a shared space project in Sweden.

Because of the design modifications, which will be discussed further, a shared space project may involve a shift in management and communication within a city for issues ranging from emergency vehicle access to street cleaning. For instance, in Portland,

Figure 1 Skvallertorget shared space project in Sweden. *Source: Photo courtesy of Norrköpings kommun.*

Oregon, one stumbling block for a proposed curbless road downtown was confusion over which agency was responsible for street cleaning once the street and sidewalk merged and became one surface.

There is not a large body of research on shared space. This may be for multiple reasons including the relative scarcity of actual projects on the ground. These projects are not monolithic and can be created on a degree of gradation from a “pure” shared space to one with fewer elements. There are many projects that are inspired by shared space and its concepts but far fewer of pure shared space projects themselves.

History of Shared Space

While similar to historic road design before motor vehicles were introduced in the early 1900s, shared space is said to have begun with Hans Monderman, a road safety investigator in the Netherlands. The popular history says that Hans Monderman was facing budget cuts while simultaneously needing to calm vehicular traffic in multiple high-crash areas. Given the lack of budget, he decided instead to remove street signs. The resulting slower speeds and lower crash rates convinced him to pursue this technique and develop it further. He worked on more than 100 shared space projects in the European Union before his death in 2008.

Hans Monderman found his initial inspiration in the woonerven in the Netherlands. A woonerf, also called a Living Street, a Neighborhood Unit, a Play Street, or a Home Zone is a small-scale individual street or neighborhood traffic-calming project which slows motor vehicle traffic down and enables residents to enjoy their community. A woonerf creates a safer “island” in the urban environment allowing children to play and neighbors to socialize. As opposed to share-space streets, woonerven are typically low-volume residential streets and different modes do not have the same priority, pedestrians are favored. For example, if a child is playing with his/her toy car in the middle of the street, a motorist will have to wait or get out of their car and negotiate with the child before they legally can continue (Article 88a RVV of 1976), and then proceed only at walking speed—though that is the speed with which a horse “walks” (Article 88b RVV). But woonerven have a lot in common with shared space, for example, both lack curbs and use physical traffic-calming tools.

The changes wrought in the standard road environment make it unusual and requires more attention on the parts of all users. The ambiguity requires all modes to actively negotiate with each other when navigating the roadway. The change in the more familiar road design accompanied by the potential for users to use the space in unpredictable manners, encourages users to pay more attention and communicate with other road users.

Conceptual Principles of Shared Space

Because shared space incorporates urban design and traffic calming, the following sections will define these two subjects as the foundational material for understanding shared space.

Urban Design

Urban design is not easily defined. Its definitions are wide-ranging and subject to debate in some circles. They can range from historic definitions looking at design precedents to qualitative definitions focusing on goals and objectives. The design literature lists multiple elements authors consider essential to good urban design and these range from large scale and general, such as a building or parcel, to smaller scale including elements like benches or street trees. Urban design elements also may be classified with respect to movement (roads, sidewalk) or barriers (walls, edges). For example, the American urban planner Kevin Lynch, in his most famous work, the *Image of the City* (1960), discusses how people take in information of streets, sidewalks, and other channels in which people travel by observing edges (perceived boundaries such as walls, buildings, and shorelines); districts (relatively large sections of the city distinguished by some identity or character); nodes (focal points, intersections or loci); and landmarks (readily identifiable objects which serve as external reference points).

In this chapter, urban design is defined as the creation of spaces and opportunities in the public realm by the function, sensitive, and flexible apportionment of space and structure with regard to users, environment, and infrastructure while encouraging the use and interaction of the public (Duncan, 2016). The appropriate scale for shared space is site-specific and primarily focused on human-scaled elements such as benches, street trees, and paving. It must be noted, though, that the larger scale aspect of urban design plays a role in the siting of shared space projects themselves.

Traffic Calming

The human body is not designed for impact at high speeds, and the death rate of vulnerable users goes up significantly with vehicle speed. While the literature varies on the specific vehicle speeds involved, in general, a pedestrian's chance of surviving a vehicular impact drops with increasing vehicle speed. Depending on multiple variables (Jurewicz et al., 2016; Kröyer, 2015), a pedestrian's chances of surviving may range from an approximately 90% survival rate at 30 km/h (20 mph) vehicle speed to a less than 50% survival rate at 50 km/h (31 mph). Pedestrians hit by motor vehicles moving at 40 mph have approximately an 85% chance of dying. Survival rates also vary depending on type of crash (head-on versus side impact) (Jurewicz et al., 2016), vehicle type (SUVs and large trucks with higher profiles), and age of person hit (Kröyer, 2015). The very young and old will have higher fatality rates at lower speeds with people 75 and older having the lowest survival rates. It is essential to recognize that the fatality rate for vulnerable users increases by almost 3% as vehicle speed increases by 1 mph. There is a clear link between survivability and speed with faster vehicle speeds being more deadly.

Traffic calming slows road users down and can be physical or psychological (Elvik, 2001; Kennedy et al., 2005). Effective traffic calming is the application of various calming elements used together to slow road users down. This works best when the elements are used in an integrated system rather than in isolation. Speed humps and bumps are the elements most commonly associated with standard traffic calming by slowing drivers with a physical element in the road. Other forms of physical traffic calming include bulb outs, chicanes, and traffic circles, which all deviate the path of the road users. For more detail, see article Speed-Reducing Measures. These physical forms often are used in shared space designs in conjunction with the entry monuments (Fig. 2).

Figure 2 Example of entry monument. Source: Photo by author.

Figure 3 Example of textured and paving patterns. *Source: Photo by author.*

Psychological traffic calming includes techniques such as visually narrowing a roadway by introduction of elements such as trees or street furniture as well as painting the road (see The City Repair Project) or paving it with alternative materials (Fig. 3). It also includes designing ambiguity into the space removing road elements as well. Psychological treatments work best when used in conjunction with physical calming methods. It is interesting to note that sometimes lack of paint can also make the road seem narrower. If you drive down a street with a centerline and it consists of two 3.25 m lanes, the lane you are driving in will look slightly wider than the oncoming lane because of the perspective you see it from. And, the 3.25 m lane will seem wide enough to allow fairly high speeds. If we remove the centerline, the road will seem slightly narrower than 6.5 m, and you are likely to slow down when there is oncoming traffic.

Risk

This is perhaps the most controversial aspect of shared space. Engineers are trained to design risk out of roads by designing for passive safety but shared space projects intentionally bring perceived risk back. Some research literature finds that the lack of risk in the environment may make people engage in riskier behavior (risk homeostasis or at least risk compensation) (Wilde, 1998), and making roads feel less safe will actually encourage less risky behavior. This concept is not without its critics but there are multiple studies, which support it. Though, optimal may be to make it seem unsafe by using certain design elements but actually have redundant safety in the system if possible.

An example of a controversial design element introducing risk can be found in the original woonerven designed in Delft. These included new elements—such as planters and boxes—placed so that a child could hide behind them, and then suddenly jump out in front of a motor vehicle. The intent was that drivers would go “dead slow” rather than drive at walking speed at those places. That can be considered part of the “unpredictable” design principle mentioned earlier. When woonerf principles were adopted for use in other countries in the late 1970s, such as opholds- og legegader in Denmark, these sight obstructive elements were eliminated. The opholds- og legegader also allowed slightly higher speeds than woonerven, up to 15 km/h (9 mph). And, Denmark at that time also introduced shared-space streets called Stilleveje for use on busier streets with allowed speed of 30 km/h (19 mph). Both these street types seemed revolutionary for Danish cities where the default speed limit—applied to most urban streets—was kept at 60 km/h (37 mph) until April 1985, longer than in other Scandinavian countries, which had been using 50 km/h as the default speed limit since much earlier.

Elements of Shared Space

As discussed, shared space encompasses both urban design and traffic calming. There is overlap between them, and a successful project integrates both. There is a general catalog of “expected” elements associated with shared space; a complete, or “pure,” shared space project typically will have the following elements in the design. First, the curbs will be removed from the roadway blurring the segregation between vehicle drivers and people walking. All lane markings, including the centerline, will be removed. All street signs will be removed as well. Removing the curbs flattens the road and adjoining sidewalks to give the project the impression of a plaza or public square. The paved surface of a shared space design will have the paving typically go from building face to building face with no distinction made between road and pedestrian space. The resultant plaza will be paved in geometric designs with textured pavers. These designs will help direct road users while the textured pavers help less able users navigate the space as well as further indicate a change from standard road space to shared space. The shared space also will include street furniture such as street trees, seat walls, benches, and light fixtures to humanize the space and create areas where people may sit and socialize. Finally, a “pure” shared space

will have entry monuments. These serve to alert road users that they are entering a space that differs from the standard roadway and they need to stay alert. All of the above contribute to creating spatial ambiguity for drivers as well as making it feel more welcoming to nonmotorized users.

Benefits of Shared Space

The concept of shared space lists multiple potential benefits to these projects. These include:

Place-making and improved sense of community: By giving the roadways back to the people through calming and design, the community may be more willing to gather and use the space for more than just travel. By creating a place where people want to be, where they can have pride of place, place-making can enhance a community. (Karndacharuk et al., 2014)

Quality of life: Beyond improving the quality of life through improved community, shared space projects can improve quality of life through safer roads, lower vehicle speeds, reduced congestion, and improved accessibility options for some user groups.

Economic growth: Shared space projects have been linked to economic revitalization of the areas around the projects. Research has found increased property values and improved economic development opportunities.

Safety: As discussed previously, the decrease of vehicle speeds contributes to safer streets for all users. There may be a decrease in crime as well due to what Jane Jacobs called “ . . . eyes on the street.”

Traffic flow: Shared space has been shown to improve throughput in multiple projects such as Poynton and Coventry (discussed below). Despite slowing traffic down, the delay is decreased due to traffic not being stop and go.

Examples of Shared Space

Initially, in the Netherlands, shared spaces were only installed in quiet, low traffic areas. Over time, it was found that these designs could work in areas with higher motor vehicle traffic volumes than initially thought. Shared space, however, is not appropriate for all roads. Instead it is best implemented in areas in need of traffic calming, especially in sites with heavy (or desired increased) nonmotorized traffic. This works best in commercial and residential areas.

It can be difficult to accurately quantify the number of shared space projects as many people count all pedestrianized spaces toward this number of shared space projects. For instance, the United Kingdom has many shared space projects; however, the reported number of projects on the ground ranges from 20 to more than 100. Examination of some of the supposed shared space sites shows that some road projects classified as shared space may be wrongly classified as shared space. For instance, some were included due to being a pedestrianized zone. (It should be noted, shared space differs from shared-use paths. Shared-use paths are a form of nonmotorized infrastructure typically shared by pedestrians and bicycle riders. They remain physically separated from motor vehicle traffic by either a barrier or open space.)

As it has been discussed, a shared space design can take many forms. It will be site specific. The following section will discuss a few projects to illustrate the range of possible designs.

Poynton, United Kingdom

Poynton’s shared space project is one of the United Kingdom’s showcase projects. This project has received significant publicity due to both its innovative design as well as a good publicity scheme.

The village of Poynton’s central intersection had serious congestion issues with a significant amount of commercial truck traffic. Poynton chose a shared space retrofit because the road running through the center of town, north to south was dominating the village and decreasing quality of life. The residents were subjected to long waits while trying to cross the main road in their own village, pollution, noise, etc. The British urban designer, Ben Hamilton-Baillie, removed the entire existing road infrastructure, including traffic signals, and converted the large intersection to shared space. This complex intersection was designed with intricate and textured paving patterns forming a double roundabout.

Ashford, United Kingdom

The Elwick Square plaza is a good example of a large shared space intersection. It is unusual in the United Kingdom for its street furniture as well as its size. Elwick Square has many of the standard shared space elements. There is textured paving in geometric patterns and a seating area with vegetation within the plaza as well as a seat wall at a spot in the site where bicycle riders often stop to wait to cross (Fig. 4).

Note that the marked crosswalk (Fig. 5), also present in other shared space projects, is not considered a “pure” shared space element. However, its inclusion represents the flexibility of the shared space concept and the needed responsiveness of listening to the public when designing these spaces. For further understanding of this project, Moody and Melia (2013) researched pedestrian movements through this intersection, and Duncan (2016) analyzed bicyclist behavior.

Figure 4 The Elwick Square project illustrating the use of street furniture, landscaping, and textured paving. *Source: Photo by author.*

Figure 5 A portion of Elwick Square shared space intersection with marked zebra crosswalk. *Source: Photo by author.*

Coventry, United Kingdom

The Coventry University shared space intersection is not considered a “pure” version. The modifications on the scheme in this intersection include multiple large, stone bollards to protect the corners from vehicle drivers. The space also utilizes colored paving instead of textured paving—an affordable and lower maintenance option. There are three zebra crossings near this intersection. One can be seen with its yellow lights farther back in [Fig. 6](#). However, it can be seen that the space is level and lane markings and road signs have been removed. The space is still ambiguous and receptive to all modes. This is an illustration of the range-shared space projects can take.

It is also more common to put shared space projects in on straightaway instead of intersections. It is a simpler/less complicated task but leaves the intersection unmodified so that it remains the most dangerous section for vulnerable road users.

Road Safety and Crashes

Comparing crash rates of shared space projects can be difficult. Many projects are newer and data are often not available or not enough time has passed since project installation to gather crash data on the new design. Another potentially confounding issue is that minor crashes may not always be reported to the appropriate reporting agencies.

In 2017 a serious car crash occurred on Exhibition Road, a shared space project in London. A driver injured 11 people after driving into a crowd along Exhibition Road leading to increased calls by the media to eliminate shared spaces in the United Kingdom. Already a contentious subject in the United Kingdom, the Chartered Institute of Highways and Transport (CHIT) responded and performed a study on the crash rates of existing UK shared space projects. The Institute found crash rates either

Figure 7 Skvallertorget before conversion to shared space. *Source: Photo courtesy of Norrköpings kommun.*

decreased or stayed unchanged after project completion. Other studies have found similar results, or that in some cases the crash rate increased but the crash severity decreased. In other words, there were fewer serious crashes and more minor collisions. However, crashes are rare and most of the projects on the ground have not shown any changes in crash rates (Karndacharuk et al., 2014). The crash rates that have been measured have shown that the crashes that do happen are more minor due to lower speeds.

Another example of changing crash rates is the Skvallertorget space in Norrköping, Sweden. A higher traffic intersection with approximately 13,000 vehicles/day (Fig. 7), the shared space site is at an important intersection in central Norrköping.

The intersection was changed from a standard intersection to a shared space designing in uncertainty as well as incorporating elements such as textured and patterned paving. See Fig. 1 for Skvallertorget after conversion to shared space. The new plaza showed a decrease in the number of crashes and vehicle speeds after project completion.

The primary goal of shared space is to slow vehicle traffic down and make spaces more livable. Livable in this case translates into a safer, more welcoming environment for nonmotorized road users. The research on shared space has shown that the ambiguity of these spaces has the effect of slowing drivers down. This also leads to safer roads for all users. An added benefit of slower speeds is improved throughput, too which actually leads to less delay to motorists.

Shared Space Debates

Concerns regarding these spaces are frequently expressed by elderly, disabled, and/or visually impaired road users. These user groups may feel less protected while crossing these spaces than in more standard road layouts. One ongoing debate in the United Kingdom concerns the potential difficulties and concerns shared space causes people with visual impairments (Parkin and Smithies, 2012). There have been research articles [focus groups] looking at the impact these road designs have on this user group. One concern from this group is the confusion it may cause guide dogs (Norgate, 2012). This has led to a recent decision in the United Kingdom to put a pause on shared space projects and build no more of them pending further investigation.

There is also an increased interest in more segregation of modes on roads. This can be seen in the 8–80 movement where projects are designed to be safe and comfortable for users of all ages. The increasing number of cycle tracks, protected bike lanes, and protected intersections are indicative of this. Some argue that this means that shared space projects are no longer appropriate. However, segregation of modes is not always the best use of a site due to limitations such as available space or a project's goals and objectives.

The use of design to influence behavior relies on the belief that all modes will respond to the road treatment similarly. Research has shown, however, that shared spaces may not always perform as designed. In the United Kingdom, for instance, a large percentage of nonmotorized users, pedestrian, and cyclists, do not cross freely, communicating with drivers. Instead, many of these users skirt the edges minimizing their interactions with motor vehicles. Culture, education, and time are all factors in how the road is navigated by different modes. In some cases, nonmotorized users may adapt and grow more comfortable with the space and use it more as desired.

Concerns about these projects may vary from country to country. In the United States, designers and DOTs are reluctant to put in any project that varies from transportation guides like the AASHTO. The fear is of litigation. In the United Kingdom, the strongest anti-shared space group is the visually impaired group.

Discussion and Conclusions

As there is growing recognition of the need to make transportation safer and more welcoming to nonmotorized users, there will be more ideas on how to design and build safer streets. Shared space is one of those options—like mode separation, is one of many possible tools in a community's toolbox.

This technique's history and its continuing controversies show how important it is to include the public in the planning and design phases. Listening and addressing concerns raised can help the community feel more comfortable about the new space and mitigate future issues. Some elements, which may help concerned users, include more tactile paving, street furniture, and inclusion of refuge areas, if possible. An example of this is the Ashford project where a pocket of trees, benches, and small wall are placed along the path where vulnerable road users most typically cross.

Current evidence indicates these spaces are safer despite feeling riskier to road users. However, it is still not clear that shared space and its riskier feeling provides a more welcoming environment for nonmotorized users—especially for the visually impaired road user. The questions will remain—how can these more democratic spaces be welcoming to all users? Further research, including analysis of existing projects and modeling of new ones (VR and temporary) will be needed to improve the concept for more countries.

Designers and engineers have to design for the space and circumstances they have. Each situation is unique. Because shared space is both design and engineering, there are no set answers to a transportation problem. Instead, designers need to approach the problem holistically by looking at the issues, the users, the goals of the municipality, the adjacent land uses, and so on. The elements of shared space alone do not make a successful, or unsuccessful project—the integration of the elements best suited for the roadway and the community are essential to the success of the design.

The concept of shared space is a controversial idea to many planning agencies and departments of transportation. The idea of making something less segregated and seemingly less safe is uncomfortable for public officials and most road users. Public agencies often water down a shared space design due to concerns about safety by installing bollards, paint in bicycle lanes, and so on. What matters is that the design is site sensitive and addresses the concerns of the community and road users of all modes. The combination of urban design and traffic calming can allow for creative options to address road sections in need to improvement.

Glossary

abutment End support of a bridge deck or tunnel.

arrester bed Sand- or gravel-filled lane adjacent to a steep downhill grade section intended to allow vehicles that are having braking problems to safely stop.

breakaway support Roadside support designed to yield or break when struck by a vehicle.

bridge parapet Safety barrier mounted on bridges, culverts, or retaining walls.

crash cushion Energy absorbing device that prevents an errant vehicle from impacting fixed objects by gradually decelerating the vehicle to a safe stop or by redirecting the vehicle away from the obstacle.

curb Raised edge at the side of the roadway or outer side of shoulder.

cut slope Earth embankment sloping upward from the roadway.

ditch Drainage channel that runs parallel to the road.

fill slope Earth embankment sloping downwards from the roadway.

median Area that separates opposing traveled ways in a divided highway.

roadside Area beyond the edge line of the traveled way.

roadway Part of a road designed to be used by vehicles.

run-off-road crash Type of crash where an errant vehicle encroaches into the roadside and either overturns or collides with a non-traversable obstacle or with the terrain.

safety barrier Longitudinal vehicle restraint system.

safety zone or clear zone Strip of land adjacent to the traveled way that is cleared of roadside hazards to afford the driver of an errant vehicle the possibility of regaining control or stopping the vehicle.

shoulder Part of the roadway contiguous with the traveled way available for the accommodation of stopped vehicles and for emergency use.

shoulder rumble strip Longitudinal warning device made of a series of indented or raised elements installed on the shoulder near the outside edge of the travel lane to provide an audible and or tactile warning to roadside encroaching vehicles.

sidewalk Area reserved for pedestrian traffic that is separated from the carriageway by a curb.

slope Ground that forms a natural or an artificial incline.

slope rate The relative steepness of a slope expressed as a ratio of its vertical height to its horizontal length.

traveled way Part of the roadway reserved for vehicular travel.

vehicle restraint system Roadside device designed to contain or to redirect an errant vehicle.

Introduction

Roads are designed in principle to accommodate vehicle travel on the traveled way. Nevertheless, vehicles occasionally encroach beyond the edge of the traveled way either intentionally to make emergency maneuvers around objects blocking the roadway or to make emergency stops or unintentionally as a result of the loss of control of the vehicle by the driver. Consequently, the conditions of the area that lies beyond the edge line of the traveled way are important both for road operation and for traffic safety. Properly conditioned and maintained roadsides complement the functions of the roadway and contribute to integrate the infrastructure into its environment. Additionally, roadside conditions have a major effect on traffic safety as a significant part of road traffic fatalities result from uncontrolled road departures.

There are multiple factors that may contribute to the loss of control of a vehicle, including abrupt maneuvers performed to avoid an imminent collision, speeding, distracted driving or drowsiness, driving under the influence of alcohol or drugs, etc. Preventive measures are taken to prevent unsafe driving patterns that increase the risk of vehicle control losses, mainly through the implementation of targeted education and enforcement schemes.

Connected-vehicle and automated-vehicle technologies also have the potential to enhance highway safety by simplifying driving tasks and facilitating that the drivers perceive hazardous situations in time to adopt the adequate decisions and to perform the necessary driving maneuvers while maintaining control of the vehicle.

The risk of drivers losing control of their vehicles can also be reduced by adapting the geometric design of the roads to drivers' expectancies, and by providing ample sight distances at critical road sections, implementing effective road signing, marking and lighting, installing shoulder rumble strips (**Fig. 1**) ([Griffith, 1999](#)), and maintaining pavement regularity and skid resistance at adequate levels. Horizontal curvature and longitudinal grade also have an influence on vehicle encroachment frequencies and on the angle and speed of road departures, which in turn are important factors influencing the severity of roadside crashes.

Early research by Stonex in 1960 concluded that at that time 35% of traffic fatalities in the United States occurred as a consequence of roadside encroachments and identified a number of factors that contribute to increase ROR crash severity, including the presence of non-traversable obstacles in the vicinity of the roadway, steep roadside slopes, deep ditches, and inadequate guardrail terminal configuration.

Figure 1 Shoulder rumble strips.

Roadside Hazards

Once an errant vehicle leaves the roadway and encroaches on the roadside, both the likelihood of it crashing with an obstacle or rolling over and the severity of crashes that cannot be prevented need to be minimized. To this respect, the existence of unprotected non-traversable obstacles on the roadside, their offset from the roadway edge, and the gradient of the side slopes are the main risk factors ([Pardillo et al., 2010](#)).

Obstacles

The existence of rigid non-traversable objects in the vicinity of the road is a major factor of roadside risk. In particular, motorcyclists lack the protection of the vehicle bodywork in the event of a loss of control or of stability and are much more likely to get injured if they hit fixed objects or uneven surfaces.

Figure 2 Traversable roadside ditch.

Figure 3 Road and roadside profile.

Roadside obstacles include trees, utility and lighting poles, signposts, rocks and boulders, bridge and overpasses pillars and abutments, culverts and culvert ends, headwalls and drainage pipes, and blunt or ramped guardrail terminals that do not bend toward the roadside. Other obstacles, such as embankments, slopes, ditches, rock face cuttings, retaining walls, and closely spaced trees, extend along a length of the roadside constituting continuous hazards. Vertical falls associated to terrain configuration or to traversing bridges or viaducts pose also a severe roadside risk.

Drainage channels and ditches perform the vital function of collecting and conveying surface water from the roadway. Deep ditches with steep sides can cause errant vehicles to overturn or collide against their back slope especially where rock cuts form the back of the ditch (Viner, 1995). Design guides recommend designs of roadside ditches with fore slope and back slope rates of 1V:6H to prevent rollovers and collisions. These configurations are primarily seen on motorways and other higher-order roads (Fig. 2).

Curbs serve multiple purposes including drainage control, pavement edge delineation, and pedestrian walkways delineation. Vehicles can readily cross-mountable curbs provided with flat sloping faces and with a height that does not exceed 0.1 m. Non-mountable curbs can destabilize vehicles and even cause rollovers when hit.

Side Slopes

Side slopes are constructed to ensure the stability of the roadway. Height, slope rate, and stability of the side slopes, particularly fill slopes, are decisive for rollover prevention and control recovery in the event of uncontrolled roadway departures. Three elements of the slope, the top or hinge point, the fore slope, and the bottom or toe of the slope, need to be considered (Fig. 3).

When an errant vehicle crosses a slope at excessive speed, it may become airborne in crossing its hinge point causing the loss of steering control. Once the vehicle has passed the hinge point and is traversing the fore slope, the driver can attempt a recovery maneuver or reduce speed if the gradient is not too steep and the soil is stable. Nevertheless, in many cases the toe of the slope is reached and consequently a smooth transition at this point is required.

Unobstructed fill slope rates of 1V:6H or lower provide the best conditions for vehicle control recovery, but transverse slopes of 1V:4H or flatter are also classified as recoverable. If such slopes are relatively smooth and traversable, motorists who encroach on them can generally stop their vehicles or slow them enough to return to the roadway safely. Nevertheless, unstable soils may cause

rollovers on side slopes that are otherwise safe. It is also important for control recovery that the hinges and toes of fill and cut slopes be round off (Zegeer et al., 1988).

Embankment slopes between 1:3 and 1:4 may be considered traversable, but non-recoverable, if they are smooth and free of fixed objects. A vehicle will normally not roll over on them, but the driver will not be able to recover the control of the vehicle. The vehicle will therefore end up at the foot of the bank if driving off the carriageway onto such slopes. In addition, back slopes of 1:3 or flatter make it easier for motorized equipment to be used in maintenance operations.

The possibilities of recovering vehicle control with side slope rates over 1:3 are severely compromised. At the same time the probability that the vehicle overturns increases substantially.

Unprotected embankments with gradients steeper than 1:2 pose a high risk of vehicle rollover and significant consequential injury if a vehicle veers off the carriageway. The combination of embankment height and side slope rate also has an effect on the severity of the crashes. Based on studies of the relative severity of encroachments on embankments versus impact with roadside barrier, the installation of a roadside barrier is recommended for embankment heights starting at less than 1 m.

On cut slopes, the slope rate and the shape of the transition between the ditch and the back slope are decisive for how a vehicle will behave when it drives off the road. On rising slopes flatter than 1:2 with a soft transition from the roadway to the slope and no other roadside hazards the driver has good possibilities of slowing down and regaining control of the vehicle. Protruding large stones and rocks located less than 2.0 m above the roadway must be blasted away or treated as hazardous roadside obstacles. Steep cut slopes with rising gradients of more than 1:2 are considered continuous non-traversable obstacles.

Safety Zones

To achieve forgiving roadsides, safety zones, also referred to as clear zones, are established by conditioning a strip of terrain adjacent to the roadway to minimize the likelihood of rollover occurrence and to provide the driver with an opportunity to regain control of his vehicle and come to a gradual stop or return to the carriageway in a controlled manner, without being a hazard to other vehicles (Thompson et al., 2005).

A safety or clear zone may consist of a shoulder, a recoverable slope, a non-recoverable slope, and/or a clear run-out area. Within the safety zone, hazards should be removed or relocated beyond its limits, substituted by passive safe types, or protected with vehicle restraint systems.

Shoulder width is an important safety feature as it contributes to increase the chances of correcting the trajectory of errant vehicles. Shoulder widths on freeways usually range from 2.5 to 3.0 m. For single-carriageway roads there is much more variability. Usual widths are 1.5–2.0 m for main rural roads in flat or rolling terrain, 0.75–1.5 m for mountain roads, and 0.5–1.0 m for local roads. Paved shoulders allow for a better control of an errant vehicle.

Although the risk of collision with an obstacle drops substantially after the first few meters, there still is a possibility that encroaching vehicles may reach farther distances from the roadway edge, and hence safety zones should be as wide as technically and economically feasible. As extending the safety zone implies increasing costs, the recommended safety zone widths are determined on the basis of cost-efficiency analyses depending on the class of road, the expected traffic volumes and operation speeds, the slope gradients, and the road geometry. Recommended clear zone widths range from 2.0 to 3.0 m for low-volume, low-speed roads up to 11.5–14.0 m for high-volume, high-speed roads.

Footpaths and cycle tracks that run along roadways with speed limits above 90 km/h should be aligned outside the safety zone of the roadway. This is also recommended for lower speed roads when pedestrian volumes are high. Otherwise, when footpaths and cycle tracks lie inside the safety zone along roadways with a speed limit of 70 or 80 km/h there ought to be a traffic divide of at least 3.0 m between the traveled way edge and footpath/cycle track, and of at least 1.5 m limited by deflecting curbstones when the speed limit is 60 km/h (Fig. 4). If the traffic divides are narrower, safety barriers should be installed to protect the pedestrians.

Figure 4 Traffic divide between the traveled way and the cycle track.

Within the safety zone, the alternatives for treating the existing hazards in order of priority are as follows:

1. Removing the hazards or moving them beyond the safety zone.
2. Modifying the hazards to render them safe. This can be achieved depending on the cases by flattening the slopes and rounding off its tops and bottoms, blasting road cuttings to obtain an even surface, and using closed ditches, collision-safe noise barriers, and earth mounds or catchment ditches as an alternative to the installation of safety barriers.
3. Replacing hazardous roadside supports with passive safe structures.

Passive safe supports are designed to break or deform in a controlled way when struck by a vehicle thus lessening the impact energy that is transmitted to the vehicle and minimizing the damage both to the vehicle and to its occupants. This can be achieved in the following two ways:

- a. Using poles made of materials that yield and crush at point of impact and absorb energy in the process.
- b. Installing breakaway devices at the base of posts and columns. The bottom flange of the pole is bolted to a frangible base plate that allows the post to slip and break away on impact. The release mechanism may be a slip plane commonly made of heat-treated cast aluminum, plastic hinges, fracture elements, or a combination of these.

Lighting columns, utility poles, and signposts are not considered a hazard if replaced with equivalent passive safe types that have been positively tested in accordance with the applicable roadside hardware standards.

4. Shielding the hazards with vehicle restraint systems.

Vehicle Restraint Systems

Vehicle restraint systems are installed on the roadsides to prevent vehicular penetration and to redirect errant vehicles away from a roadside or median hazard. There are different types of vehicle restraint systems including safety barriers, bridge parapets, crash cushions, and truck arrester beds. Their general purpose is to reduce as much as possible the extent of damage and injuries when uncontrolled vehicles leave the road. In addition, in certain situations there is also a need to protect road users near the road against errant vehicles, to shield critical installations located near the road such as railways, fuel tanks, etc., to prevent uncontrolled vehicles from falling down onto railroad tracks or roads, or into rivers passing under the road (Gardner: Bridge safety), and from damaging road structures that could cause serious consequential damage if impacted.

Hitting vehicle restraint systems may cause damage to the vehicle and its occupants. Therefore, they should be installed only if it is more hazardous to run into the hazard that they shield than to drive into it.

Safety Barriers and Bridge Parapets

Safety barriers are longitudinal restraint systems. They are used to prevent errant vehicles from hitting non-traversable obstacles, overturning on steep side slopes, or falling from a height. Depending on the amount of barrier deflection that takes place when it is struck, safety barriers are classified into three categories: flexible, semirigid, and rigid.

Bridge parapets or railings are safety barriers specially designed to be mounted on the verge of the road on bridges, viaducts, culverts, or retaining walls to prevent vehicles, pedestrians, or cyclists from falling off the edge. Bridge railings are a structural extension of the bridge, differing from other barriers that usually are set in, at, or on soil (Fig. 5).

Figure 5 Bridge parapet.

Figure 6 Semirigid safety barrier.

Flexible systems generally consist of steel wire ropes mounted on weak posts. The flexibility of the system absorbs impact energy and dissipates it laterally, which reduces the forces transmitted to the vehicle occupants.

Semirigid systems consist of galvanized steel rails and steel or hardwood posts (**Fig. 6**). When impacted by a vehicle, the rail deflects and the vehicle is led along the safety fence until it stops, or it is redirected back onto the carriageway by effect of the combined tensile strength of the rail and flexural strength of the posts. Lateral restraint is provided by the posts. The impact energy transmitted to the vehicle and its occupants is greater than for a flexible system but lower than for a rigid system.

Rigid barriers such as concrete barriers do not suffer large permanent deformation on impact. Concrete barriers were developed in the United States of America in the 1960s for use on narrow medians. Over the years, different profiles have been developed, each one having a vertical base section, a flatter lower section and then a taller and steeper upper section. The most widely used nowadays are the New Jersey barrier (**Fig. 7**) and the F-shaped barrier.

Rigid barriers are designed to work at limited impact angles, usually not greater than 20 degrees. An errant vehicle that strikes a rigid barrier at a sufficiently low angle will tend to ride up the lower slope. The lifting of the vehicle and the deformation of the vehicle suspension absorb vehicle energy, slowing it down and pivoting it away from oncoming vehicles and back into traffic heading in its original direction. Kinetic energy is dissipated by the friction of the vehicle side against the almost vertical upper face of the barrier and by the deformation of the bodywork on collision.

The selection of a barrier system for a particular location depends on the required containment level and on the space available for accommodating lateral deflection upon impact without reaching the hazard. When hit at the specified angles and speeds, all safety barriers are capable of redirecting and/or containing an errant vehicle without imposing intolerable deceleration forces on the vehicle occupants. Nevertheless, more rigid systems may cause more severe damages if impacted at sharp angles. In spite of this, they are required when the offset to the object is low and when it is necessary to contain heavy vehicles.

Safety barriers installation requirements define the length of need or total length of barrier needed to shield an area of concern, the lateral offset to the hazard, the barrier height, and the barrier terminal conditions.

Barrier Terminals and Transitions

A safety barrier terminal is a special structure that is installed at the beginning or end of a safety barrier to anchor the leading end without introducing additional hazards for vehicle occupants. They are required to have specified impact performances to ensure that a vehicle that strikes them either drives through the termination and gradually stops or is redirected into the carriageway without significant injury to the driver or the passengers.

Terminals may be flared or tangent. The alignment of flared terminals diverges from the alignment of the roadway edge to redirect vehicles back onto the carriageway, while the alignment of tangent terminals is parallel to the roadway edge. Tangent terminals need to be energy-absorbing devices that have to be tested in accordance.

Safety barrier transitions connect two safety barriers of different geometry and/or containment levels and/or lateral deformation. Common locations for transitions are connections between bridge parapets and roadside safety barriers. Transitions need to be configured to provide a gradual change in the stiffness between the two connected systems thus ensuring a safe performance if a vehicle strikes the transition area.

Motorcyclists and Cyclists Protection Devices

Safety barriers may pose a risk of injury to motorcyclists and cyclists. The most serious incidents that can cause serious injuries, sometimes fatal, occur when they fall and hit a sharp edge or a protruding part or when a direct impact of the motorcyclist against the

Figure 7 New Jersey concrete barrier.

Figure 8 Safety barrier with secondary rail for motorcyclist protection.

post barrier occurs. In consequence, safety barriers with sharp edges or corners with a radius of less than 0.009 m or protruding parts that can be struck should not be used unless they are effectively protected.

Protection systems designed to reduce the severity a motorcyclists' impact with a safety barrier fall into one of three categories: individual post protector, a secondary rail, or a barrier designed with motorcyclist safety incorporated. Safety barriers with a motorcyclist protection device should be erected in locations where there is a significant risk of motorcyclists rolling over and impacting the barrier such as the outer bends of roads with a significant level of motorcycle traffic (Fig. 8).

Figure 9 Crash cushion.

Crash Cushions and Arrester Beds

Crash cushions are energy absorbing devices used to prevent errant vehicles from head-on impacts with fixed objects at locations where the obstacle cannot be removed, relocated, or made breakaway, and cannot be adequately shielded by a longitudinal barrier.

Crash cushions (sometimes called energy absorbers or impact attenuators) are designed for protecting a point hazard. In contrast with safety barriers, crash cushions are designed for impacts at the end points of their structures, as well as impacts along their sides. They decelerate a vehicle over a short distance in front or side collisions, or which redirects it past a hazard. Commonly used crash cushions absorb the kinetic energy of the impacting vehicle by means of compression of plastically deformable components that are supported by a rigid structure (**Fig. 9**) or by transfer of the momentum of the vehicle to an expandable mass of material, usually sand contained in plastic material barrels.

Depending on their performance for oblique impacts crash cushions are classified into two categories:

- Redirect: Designed for oblique impacts and can behave like a safety barrier for short sections.
- Non-redirect: With no capacity for oblique impacts.

Arrester beds are a special type of vehicle restraining system typically a long, sand- or gravel-filled lane that allows a moving vehicle's kinetic energy to be dissipated gradually and is connected to the main roadway by an escape ramp. These devices are generally located on long steep descending gradients and designed to accommodate large trucks or buses. They are provided to enable vehicles that are having braking problems to decelerate and stop safely without crashing. When terrain conditions allow it, the escape ramp is angled away from the downhill road so that the arrester bed lies on an ascending gradient thus taking advantage of gravity in dissipating the kinetic energy of the vehicle (**Fig. 10**).

Figure 10 Arrester bed.

Testing and Approval of Road Restraint Systems

Prior to be approved for use in public roads, these systems are subject to exhaustive safety testing.

Tests are specified at different containment or test levels defined in terms of vehicle type and mass, and impact speed and impact. Approval criteria for each test or containment level impose conditions in relation with the structural adequacy of the system, the limitation of occupant risk, and the postimpact trajectory of the vehicle. The tested systems impacted by a vehicle of the specified mass at the specified speed and impact angle must contain and redirect the vehicle in a controlled and predictable manner with no overriding, overriding, or penetration. Furthermore, fragments of the system cannot penetrate the passenger compartment, the vehicle must remain upright during and after the collision, and the passengers must not undergo excessive impact or deceleration.

In the United States, testing conditions and requirements for roadside hardware are specified in the Manual for Assessing Safety Hardware (MASH), while in Europe the European Road Restraint Systems standard EN 1317 is applied.

Within MASH six test levels are defined. Test levels 1 and 2 are designated to qualify the features for work zones, lower service level roadways, and local roads. Test level 3 covers both passenger cars and pickups. The impact speed is 60 mph (97 km/h) with an impact angle of 25 degrees. It is applied to qualify a wide range of higher service level roadways and high-speed highways. Test levels 4–6 are designed to test the ability of restraint systems to contain heavy vehicles. Tests are conducted with single unit trucks at 56 mph (90 km/h), tractor trailers at 50 mph (80.5 km/h), and tractor-tank trailers at 50 mph (80.5 km/h), respectively. The impact angle is 15 degrees in the three cases.

EN 1317 defines three containment classes (normal, high, and very high) with several vehicle impact test descriptions for each class ranging from a light passenger car of 900 kg of mass at 100 km/h with an impact angle of 20 degrees to a 38,000 kg articulated truck at 65 km/h with an impact angle of 20 degrees.

Biography

After completing his PhD in Transportation Engineering at Madrid Technical University in 1995, Dr. Pardillo-Mayora collaborated with the Federal Highway Administration Office of Technology Applications in Washington, DC from May 1996 to September 1997. Since 1998 he is Associate Professor at the Department of Transport Engineering, Urban and Regional Planning of the Technical University of Madrid (UPM) and works as consulting engineer specializing in traffic engineering and road safety studies. He has participated as principal investigator in several national and European road safety research projects including DISCAM (Tools for Designing Safe Roads and Roadsides). He has collaborated on a continuous basis with the Spanish National General Directorate of Roads as senior road safety consultant in the planning and implementation of the National Road System Safety Improvement Programs since 1992. He has collaborated as independent expert with the European Commission's Innovation and Networks Executive Agency (INEA). He is member of the Conference of European Director of Roads (CEDR) Technical Group Road Safety since 2009. He also served as a member of the PIARC International Road Safety Committee (1992–96) and of several US Transportation Research Board Standing Committees since 1999 until 2013. In 2002 he was appointed to the Task Force for the Development of the US Highway Safety Manual (ANB25T) and participated in the preparation of the Manual until its publication by AASHTO in 2010.

Introduction

Simulation in transportation provides the promise of exploring, testing, and improving human performance in hypothetical worlds that would be either too expensive or too risky to conduct in the real world. The primary uses of simulation is to either conduct research or provide training. This chapter focuses primarily on the research use of simulation, particularly in driving. Readers should have the tools to critically examine research in transportation simulation and take the first steps to conduct their own research programs. While the domain of interest here is research in driving, the issues raised should be broadly applicable across other transportation domains, along with training methods.

Simulators have been primarily used in both flight transportation and ground transportation. In aviation, simulators are primarily used for pilot training, and both the US Federal Aviation Administration (FAA) and the European Aviation Safety Agency (EASA) have different standards and levels for flight simulators, ranging from training systems for procedures to full flight simulators. In driving, simulators are primarily used for training and evaluation of human behavior in a research context. Driving simulators have been employed for civilian and commercial vehicles (cars, trucks), as well as emergency vehicles and buses.

For effective use and design of a simulator scenario in both aviation and driving, the two predominant concepts are fidelity and validity, which overlap and yet are subtly distinct and are sometimes used interchangeably. Both concepts are covered in detail, but to summarize, fidelity could be considered the realism of the simulated world or the correspondence between the elements of the simulator and the real world, while validity generally refers to whether the simulation has achieved its research or training purpose. Fidelity and validity typically but do not necessarily correspond (Dahlstrom et al., 2009).

Simulation Characteristics, Fidelity, and Validity

Fidelity is the degree to which the simulation is realistic. In theory, if the simulation is high fidelity, performance in the simulator should correspond to performance in the real world. However, there are two major problems with simulation fidelity (Meister, 1990). First, increasing fidelity is expensive, and those building simulators and simulation worlds often find themselves determining how far they can diverge from the real world, while still maintaining value and generalizability in the simulation. Second, there is a subtle problem with the definition of simulation fidelity, in that it can represent at least two different subtypes of fidelity: physical and psychological-cognitive (Liu et al., 2009). Physical fidelity indicates the degree to which the simulation replicates the real environment, and can be broken up into subtypes: Equipment fidelity, motion fidelity, and visual-audio fidelity, see Fig. 1 for examples of low and high physical fidelity driving simulators. Psychological-cognitive fidelity represents the degree to which the simulation requires the use of the underlying psychological and cognitive processes necessary in the real-world setting.

Figure 1 Images of University of Minnesota HumanFIRST Laboratory open cockpit (left) and full chassis (right) driving simulators.

Psychological-cognitive fidelity can be partially decomposed into task fidelity and functional fidelity. Determining and verifying psychological fidelity in simulation falls to methods such as task analysis (Hays, 1980). Hierarchical task analysis and task decomposition methods can guide the development of the simulation world and ensure some cognitive and perceptual components needed to perform the scenario under the research question are adequately implemented. For complex task environments, a survey of psychological and cognitive components in a simulated environment may require a cognitive task analysis, which is then integrated into the simulation with effective scenario design.

Considerations in Fidelity

In training, the focus on physical fidelity primarily arises from identical elements theory (Woodworth and Thorndike, 1901), which argues that practice leads to transfer of learning, if the stimulus elements in both the practice and testing environment are the same. Even outside of the training context, some have argued for the centrality of physical fidelity in simulation, in that perception and action are fully specified by the environment and the higher order relationships (i.e., affordances) between the participant and the environment (Stoffregen et al., 2006). Those emphasizing psychological-cognitive fidelity argue that more indirect cognitive processes moderate these participant-environment relationships and must be considered in both the research and training context. Besides the prohibitive issue of cost in designing high physical fidelity simulations, if the research question or training emphasis focuses on complex decision-making in safety critical domains, or environments with significant communication and team dynamics, then a focus on physical fidelity and face validity may be less effective than that of psychological-cognitive fidelity. This issue has been particularly relevant in aviation simulation and may emerge more often in other areas of transportation as automation and team processes become more predominant (e.g., automated vehicles) (Dahlstrom et al., 2009).

Measuring Fidelity

Verifying fidelity remains a challenge. For equipment fidelity, there are known design standards (e.g., comparison with real aircraft or motor vehicles). For visual-audio fidelity, there are metrics such as resolution, visual angle, and decibels. However, for most other types of fidelity, the metrics are less objective. The primary approach to determine the degree of fidelity has been to utilize subjective measurements (Liu et al., 2009). A typical method is to use experts or known users to rate simulation conditions on either a binary (0 or 1) or Likert (1–5) scale on what degree the simulation condition duplicated the real-world. These ratings can then be averaged to assess overall fidelity. Mathematical models have attempted to be more rigorous in their approach by building a referent or formal representation of reality, (e.g., objects, attitudes, and behaviors), derived from functional analysis and task analysis, and then use this referent and its components as the benchmark to determine fidelity in the simulation.

Scenario Design

Simulator scenario design for driving consists of specifying a road environment, a set of scenario events, and the data to be output. A temptation might exist to focus on the primary experimental event, but the entire scenario must be considered to ensure a successful design and avoid unwanted effects.

The road environment consists of the roadway itself, pavement markings, signs, and landscape surrounding the road. The entire road environment is significant to the scenario design. It is clear that the roadway and regulatory signs are important, but even the landscaping surrounding the road can influence the behavior of the driver in the simulator (Scallan and Carmody, 1999). The holistic design of the global experimental environment consisting of major roadway regions and adjacent environmental features must be considered. Most scenarios consist of several events linked by a period of driving not directly related to an event. The limitations of the simulator are a factor in scenario design. Low-workload driving on straight roads causes more fatigue than driving curved roads (Matthews and Desmond, 2002), which will impact subsequent events. A desktop-style simulator with a limited visual display is not suited for scenarios that require tracking objects in the periphery, such as crossing an intersection. Merging into traffic requires a visual system that incorporates the vehicle mirrors. Motion systems have a significant impact on lane-keeping when the participant is engaged in a secondary task (Greenberg et al., 2003). Each simulator is unique, and the characteristics of the device used must be a design consideration when creating scenarios.

Scenario events are the interactions between the driver and elements within the simulator world. The elements include other vehicles, pedestrians, regulatory and advisory signage, and environmental features. In developing a scenario, it is important to focus on conditions that create the event rather than the desired outcome, as the driver only has control over their speed, following distance, and headway (Papelis et al., 2003). Researchers must be cautious about making assumptions on how the driver will behave and design scenario events accordingly. Scenario testing and “pilot testing” are critical steps in the design of experiments to identify the range of behaviors produced from a set of event conditions and provides data on unexpected driver outcomes or challenges and problems in research protocols, in turn saving resources and time.

Data collected from the simulator is the entire purpose of running an experiment and the desired data fields should be clearly specified in the design prior to protocol creation and during the development and refinement of research questions. Research questions need to be in appropriate scope and assessed through experimental design to ensure accurate generalizability and replicability. When specifying data to be collected, fundamental measures can be used to later derive more complex information but the inverse is not true. The position of vehicles and time can be later used to derive a variety of measures including velocity, acceleration, and time headway. Direct output of higher measures (such as time headway) can be useful, but are of limited usefulness in deriving other data.

Scenario Validation

A key advantage of simulation is the ability to place participants in rare situations without harm that are capable of inducing the same sorts of emotional responses that real-world situations create (Caird and Horrey, 2011). However, balancing the ability to test extreme scenarios with the need for real-world generalization of the observed behavior is the major challenge of transportation simulation, and is partly accomplished through validation of the scenarios. Validity of driving simulation can roughly be defined as the extent to which the simulation matches the intended real-world driving target of interest, typically through comparison of simulated driving to on-road driving, naturalistic driving, self-report measures, or expert assessments. There are multiple subtypes of validity and determining what is most important in the research question or training focus helps to determine which type of validity is most important to achieve (Reimer et al., 2006). Six basic kinds of validity, shown in Fig. 2, should be considered to guide the iterative creation of a driving simulation scenario: face validity, construct validity, content validity, predictive validity, concurrent validity, and external validity.

Face validity of a simulation scenario relates to the appropriateness and relevance perceived by the observer. Achieving face validity often requires detailed design specifications and computer programming to present a high level of realism to subjects and while it is not necessarily a barrier to successful measurement, it can help create the right level of immersion to properly motivate drivers in the task. Beyond establishing visual details, achieving face validity might include the introduction of time. Notably, the types of real-world driving scenarios that result in a fatality are extremely rare per vehicle mile traveled, so recreating them perfectly is a challenge and repeated exposures in such a short exposure period diminishes the ability to elicit the intended

Figure 2 Schematic of validation steps in the iterative design life cycle of driving simulation scenarios.

response (Caird and Horrey, 2011). Countering this effect often requires introducing a surplus of mundane and uneventful road/scenario exposure.

Examining *construct validity* involves broadly determining if the performance concept (e.g., driving skills, risk taking) is being accounted for in the variance. For example, designing a simulator scenario to measure the construct of “driving skill” would likely include a series of complex maneuvers and difficult-to-avoid collision trajectories with other roadway units. Validating driving skill could involve measuring performance across two driving groups with known relative differences to ensure the expected variability is achieved. Such validation can occur within the experimental design or a priori.

Deeper within construct validity falls *content validity* which is the measure of how well the driving scenario captures all of the facets of the construct under investigation (e.g., driving performance). For example, real-world driving performance includes lateral and longitudinal control tasks to maintain position and speed (MacAdam, 2003) while avoiding hazards that are cognitively controlled with both strategic and automated processes (Ranney, 1994). Validating that a simulated scenario contains all of the requisite content (e.g., lateral + longitudinal control, hazard detection) often involves employing subject matter experts (SME). Generally, the majority of SMEs should agree that the scenario or task contains the necessary content of the task (Lawshe, 1975), although the percentage of agreement should be even higher, if the sample of SMEs is small (i.e., fewer than 10).

Predictive validity helps to serve the intention of measuring simulated driving performance to determine the likelihood of future driving outcomes in the real-world, namely the likelihood of crash involvement. Predictive validity studies that examine future crash risk often involve large sample sizes with long-term and costly examinations of self-reported or government recorded crash outcomes. Predictive validity is essential in instances where decision-making using simulated performance may result in discriminatory practices, or implementations with significant real-world impact.

An economical alternative to predictive validity to consider is *concurrent validity* in which simulation performance is tested to determine how well it correlates with intermediate outcomes or measures already validated with other metrics such as crash involvement. Simulated driving performance can be correlated with driving test performance and on-road test performance (Mayhew et al., 2011). Beyond evaluation, simulation performance may be validated against self-report measures (e.g., tendencies, driving history, etc.) and neuropsychological tests that predict driving outcomes. Alternatively, these processes can be used to identify *convergent* and *divergent validity* of which metrics are and are not correlated with driving performance.

External validity is often one of the foremost concerns of practitioners in determining the extent to which driving simulation findings should influence the world. There are a number of challenges to external validity including factors that can be controlled through experimental design, such as road choice, sample size or bias, participant fatigue, and motivation (Kaptein et al., 1996). Creating a simulated driving environment, using geo-specific databases and topographical data, based on an existing road and driving environment affords the opportunity to externally validate simulated driving performance to on-road driving performance.

The following is an example of the proposed procedure for designing and evaluating validity, as outlined in Fig. 2. In a simulated driving task across rural intersections in a driving simulator, the authors attempted to test the validity of the experimental design. Both face validity and external validity were constructed by way of high audio-visual and equipment fidelity by using a full-chassis on a motion base and a 210-degree forward arc screen, and a 7.1 surround sound stereo system, as well as the modeling of a known rural intersection (e.g., geo-specific road design). The content validity was assessed with local county engineers with experience with rural intersections who provided subject matter expert testing with representativeness scores on the simulated world, that is, infrastructure design, environmental elements, and sight distances, as well as the presentation of cross traffic speeds. Construct validity was considered by reviewing and referencing a theoretical framework of collision judgments that would be applicable in the context of intersections, in which both speed, size, and task type affect a person’s perception of collision. Because the limited proposed sample size did not allow for sufficient predictive validity, concurrent validity was instead provided. This was done by the utilization of self-report mental workload and risk perception questionnaires that were expected to covary along with the more difficult experimental trials. By considering these different forms of validity rigorously in the development process, the authors were able to have significantly higher confidence in the relevance of their results to real-world intersections.

Population and Participants

One of the greatest tenants within the field of human factors and ergonomics is “know thy user.” This principle naturally extends into the domain of transportation simulation in two significant ways. First, it is important to create your simulation design and test methods with the actual or target user population in mind. Second, it is critical to properly sample and classify your test population to ensure that your results are valid and properly interpreted. Driving performance and culture are not universal across any substantial fleet and the nuance of expected differences in simulation outcomes across sub-populations requires thoughtful consideration. Careful design of the simulated world, scenario, and tasks should account for the demographics, and the cognitive and physical characteristics of the target population. For cognitive characteristics, this includes experience and expertise level, attitudes, and individual differences within the specific domain (e.g., driving). For physical characteristics, this commonly is captured by height, reach, and physical strength. Gathering the data to define the target population may be challenging but will significantly strengthen the generalizability of the simulation to the real-world environment. Some techniques to gather this population data include surveys, interviews, and focus groups (Etches and Phetteplace, 2013).

Population demographics are most often segmented by gender, age, and experience. These three classification strategies allow blunt but useful parameters for extracting differences in metrics relating to performance, risk-taking, and subjective reporting. Additional sub-groups should be considered based on the task or research question. For driving simulation, there are a number of driver traits that have been associated with driving performance that are more difficult to ascertain through simple screening or eligibility protocols. Personality, skill level, and recent experiences may all contribute to driver performance or response to training in varying ways and must be assessed through structured surveys.

Gender is often a primary consideration for population sampling and generally should include a balanced sample of male and female drivers. In the United States, men are slightly overrepresented in early years of driving (e.g., approximately age 24 years and younger) and women are slightly overrepresented in later years of driving (e.g., age 70 years and older), but these distributions vary across regions and cultures. However, some examinations of occupational driving may not require parity in gender sampling, rather should include a representative sample of the population of focus. Stratified sampling may be required to obtain statistical power, if some subgroups are small.

Age and experience are two distinguishing factors for driving populations that are often interchangeable, that is, young drivers tend to be inexperienced and older drivers tend to be experienced, but there are exceptions to this rule. Migratory patterns may influence the disconnect between age and experience as immigrants with origins in countries where language, culture, or roadways are significantly different from their new location may result in a pronounced increase in crash risk. These changing licensing trends and evolving demographics of the driving fleet should be considered and controlled for in driving simulation population samples.

Performance in transportation simulation tends to vary based on age. Young drivers (i.e., often defined as 15–20 years old) and older drivers (i.e., defined as 65 years and older) are often the age groups that receive the greatest examinations due to their increased crash risks. These gross age classifications, however, may be too broad given known variability of performance and risks within them. Notably, young-old drivers (i.e., age 65–75 years) have been shown to have similar performance as middle-aged drivers (i.e., age 35–55 years) so it is likely inappropriate to group with middle-old (i.e., age 75–85 years) or old-old (i.e., age 85+) drivers because age-related differences would be obscured.

Simulator Sickness

Simulator sickness issues (the experience of feeling ill with their use) is a persistent challenge across multiple types of driving simulators (Stoner et al., 2011). This challenge places limitations on the population used in simulation. Although less severe and less frequent, simulation sickness is similar to the experience of motion sickness including symptoms of fatigue, headache, increased salivation, sweating, stomach awareness, and burping (Kennedy et al., 1993). The expected percentage of the population that will experience simulation sickness is reduced through necessary screening since several known factors are linked to its likelihood. In general, temporary conditions such as illness (particularly within the ear), fatigue, pregnancy, or hangover should delay simulation exposure until conditions are resolved. Permanent precluding factors include any history of motion sickness, epilepsy, or migraine.

Screening for a history of motion sickness is necessary but insufficient to eliminate all drivers who may be likely to experience simulation sickness. Potentially useful is an additional screening protocol of a brief introductory drive that is expected to mildly induce early symptoms of simulation sickness, but not so severe to unduly expose participants to triggering events who might otherwise complete the full simulation (Gable and Walker, 2013). Such measures may serve a dual purpose to acclimate individuals to the simulated environment and reduce sickness incidence rates. Assessments such as the simulator sickness questionnaire (SSQ; Kennedy et al., 1993) or the Motion Sickness Assessment Questionnaire (MSAQ; Gianaros et al., 2001) should be administered before, in between drive segments, and after completion to ensure individuals are well enough to continue or be released. Viewing the participant, directly or through a video stream, is critical to allow the experimenter to look for visual cues of simulation sickness, such as rapid swallowing, burping, mouth movements, sweating, and looking at a fixed object, since individual differences among participants may lead some to be less likely to disclose symptoms or attempt to mask symptoms.

Beyond screening, considering the simulation sickness in simulation scenario design is critical in helping to prevent its incidence rates. Considerations should include visual and temporal characteristics, optic flow, and exposure. Ensuring that the point of view for the driver matches their motion path and expectations is critical, as misalignment will induce discomfort and simulation sickness. The optic flow visually perceived by drivers will not coincide with the vestibular activation of their inner ear since true motion is not occurring. This is related to one of the several theories about the root cause of simulation sickness such as sensory or cue conflict theory (Brooks et al., 2010). Introducing stops, starts, turns, and large objects near the roadway create greater optic flow for drivers and add a greater potential for simulation sickness. Such elements may be instrumental for face validity and the research design but should be used sparingly. The detriment of the optic flow cues may be partially offset through the use of motion systems to stimulate the driver's vestibular system. These systems vary in cost and complexity, ranging from vibration or slight actuation of the cab by a few inches to greater range of motion through hexapod motion bases and track based bases where the entire vehicle moves around a large space. Finally, general guidance suggests that simulation exposure should be broken up with 5–10 minute breaks, with drives lasting no longer than 1 hour (shorter for more intense drives) and total exposure lasting no longer than 2 hours (Stoner et al., 2011).

Performance Metrics

Using a simulator for either research or training purposes requires the selection of useful metrics to determine whether a hypothesis is disproved, what patterns of behavior emerge in hypothetical scenarios, or whether training was effective. Measurements can be derived from the simulator program itself, such as the data output from the primary driving task in a driving simulator (e.g., average speed). Measurements can also be taken from other sources, such as secondary task measures (e.g., cognitive or physical tasks performed concurrently with the primary simulator task), subjective measures (e.g., attitude and usability questionnaires, mental workload scales), and physiological or neurological measures (e.g., pupillometry, eye-tracking, heart rate, functional near-infrared imaging).

Simulator Measures

For measurements derived from the simulator program, one useful organizing framework is to take a time-scale or levels of control approach. In aviation, this distinction is often made in the context of aviation and navigating tasks, in that control of the aircraft's altitude, lateral deviation, and longitudinal position is governed by direct pilot management of pitch, bank, and thrust (Wickens, 2007). In driving, the time-scale or levels of control framework can be delineated into strategic, tactical/maneuvering, and operational/control levels (Michon, 1985; Ranney, 1994). The strategic level involves control of the vehicle guided by long-term plans over the course of minutes, hours, and even days. Examples include route planning and navigation and may be assessed by posing decision-making scenarios within a driving simulation (e.g., best route choice based on some metric, goal planning). The tactical or maneuvering level of control typically involves explicit maneuvers made with the simulated vehicle and usually takes place in a span of seconds. This includes turning maneuvers, lane changes, and overtaking another vehicle. In a safety context, these maneuvers may include gap acceptance, braking and other forms of event monitoring, such as hazard detection and response (e.g., sudden braking of a lead vehicle, intruding vehicles, pedestrians). At the operational or control level, which is typically measured at millisecond time scales, the simulation scenarios are concerned with lateral and longitudinal control of the vehicle (Young et al., 2009). Examples of this include lane keeping, speed control, following behavior, and headway maintenance. See Fig. 3 for an overview of this time-scale or levels of the control framework for direct simulator measurements.

Even if distinguished in this fashion, there is still the question of exactly what measurement is used for each level and assessment task. Strategic level measurements usually comprise of choices and decisions made by the human participants, and the quality of these choices is determined by some prior referent or normative standard. For example, in a driving simulation, participants could decide which route to take upon arriving at a simulated intersection, given prior information such as travel time and complexity (Tian et al., 2011).

Tactical or maneuvering level measurements can be partially determined by the maneuver or event detection task scenario, given that the metric is also generally understood in a real-world recreation of the same task scenario. In the context of vehicle maneuvers: Turning can be measured by the degree of steering wheel turn and acceleration, although expert scoring of turning errors by participants has also been employed in this context (Shechtman et al., 2009). Lane changes may be measured by whether a lane change occurred (i.e., two or four wheels crossed over the lane line during the duration of the lane change event), and the average time to cross over the lane edge (e.g., time from two wheels to four wheels over). The lane change test (LCT) has also been used to measure the efficacy of changing lanes in the context of distraction, and primarily relies on reaction time as a metric (Mattes and Hallén, 2009). Overtaking maneuvers have been assessed looking at a count of when drivers crossed the roadway when it was not

Figure 3 Overview of timescale or levels of control framework for simulator metrics.

permitted (e.g., double lines on the simulated roadway indicating no overtaking permitted), the lateral minimum distance between the simulated vehicle and the overtaken vehicle, and lane position and speed.

In the safety context of event detection and monitoring, this is often done in the context of distracting secondary tasks to determine whether participants in a simulator respond to events while dual-tasking (e.g., reaction time to traffic lights by acceleration or foot off the brake, [Young et al., 2009](#)). Also, event detection and monitoring are relevant to hazard detection, such as measuring the braking time from event onset, such as a hidden pedestrian or stop sign ([Lee et al., 2008](#)). Measures for event detection are frequently reaction or response time based, given that the speed of response generally indicates the moment a person has spotted a hazard or a critical event. However, one could consider distance metrics from the hazardous simulated object, or utilize time-to-contact metrics ([Hancock and Manser, 1997](#)). Time-to-contact is generally the calculation of the distance between two vehicles divided by their speed, which provides an estimate of when the two simulated vehicles will come into contact with each other. For somewhat more complex safety-critical scenarios such as gap acceptance, metrics typically focus on the gap in seconds between the participant's vehicle and the oncoming vehicle along with the reaction time of the decision to cross (usually via accelerator pedal press). Also, in the context of turning maneuvers and gap acceptance, one could measure the rotation angle of the steering wheel.

Operational or control level measurements are typically consistent no matter the overall driving scenario, as it is assumed that significant variation in these measures reflects poor vehicle control, whatever the proposed mechanism behind the poor control may be, such as driver inexperience, stress, fatigue, distraction, or high cognitive load. These measures are typically concerned with lateral and longitudinal control of the vehicle ([Young et al., 2009](#)). Longitudinal control has normally been measured in terms of speed (average speed, maximum speed, variability or standard deviation of speed, and 85th percentile speed) and vehicle following (time and distance based average headway, standard deviation or variability of headway, and minimum headway). Meanwhile, lateral control of the vehicle has been assessed via lane keeping or lateral position in relation to the center of the lane (e.g., average lane position, standard deviation of lane position, and count of deviations from the lane), along with steering wheel measurements (e.g., standard deviation of steering angle, reversal rate, and steering entropy).

Psychophysiology, Eye Tracking, and Cognitive Load in Driving Simulation Research

Psychophysiology, or the study of measuring interrelationships between physiological biomarkers and cognitive activity, afford researchers with opportunities to compliment driver performance in driving simulator scenarios to help validate and discern relative psychological changes based on physiological biomarkers. Heart rate variability, electroencephalography, and electrodermal activity are common psychophysiological methods used to infer driver psychological states, mental workload, and engagement.

Eye Tracking Measures

Saccadic eye movement patterns and fixations on areas of interest are two commonly used eye-tracking measures in driving simulation studies. Saccades are defined as the movement of the eyes between brief moments of pause when fixating, or examining a set location when the eyes are stationary. Fixations and saccades are determined by equipment sampling resolution and algorithms. Changing settings for fixation duration (ms) criteria and saccadic filtering algorithms using the same data set can result in markedly different output results in analyses ([Shic et al., 2008](#)). Ensuring fixation and saccade threshold criteria fit experimental interventions (e.g., target presence, collision event) is critical for conducting a robust driving simulator experiment with eye tracking measures. Most commercial eye tracking systems provide a minimal level of control in setting dependent measures criteria, and system algorithms' underlying calculations are not readily modifiable.

Pupillometry in Task Performance and Cognitive Load

Pupillometry is a derivative measure of general eye tracking methods considering at average pupil size and variability. While driving performance measures provide useful insights into the general state of the driver, assessing dynamic pupillary changes while drivers perform simulated driving tasks can indicate task-based, time-sensitive changes in such cognitive load ([Beatty, 1982](#)). Popular methods to capture cognitive load using pupillometry are based on the mean of the pupil and its rate of diameter change, and the number of measurable changes in diameter over a period of time ([Palinko et al., 2010](#)). Rapid changes in the mean pupil diameter change rate is a benchmark method that is easily accomplished using commercial eye tracking systems.

Psychophysiology Measures

Electroencephalography (EEG) typically involves a 56–256 electrode array on a wearable cap, and provides general insight into which cortical brain regions are activated or inhibited during task performance. In studies where specific events are triggered based on participant position (e.g., lane departure), driving behavior (e.g., collision event), or instructions to engage in secondary tasks, EEG measurement techniques such as event-related potentials can be implemented to discriminate cortical brain activity between task and non-task conditions. Data can be used to provide insights into the task demands via neural activity patterns. Electrodermal activity (EDA), historically referred to as galvanic skin response or skin conductance, involves the detection of resistance via skin

Table 1 Recognized criteria for subjective mental workload measurement

<i>Criterion</i>	<i>Description</i>
Sensitivity	Measure varies with changing task demand level
Diagnosticity	Assesses qualitative differences in task demand and their causes
Selectivity or validity	Measures construct in question (i.e., mental workload)
Intrusiveness	Extent to which mental workload measurement affects primary task performance
Reliability	Measurement method consistency in repeated administrations
Implementation requirements	Resources required to use measurements (time/materials)
Subject acceptability	Participant perceived validity and usefulness of measurement

sweat as secreted across the palm or bottom of the foot. While this psychophysiology measurement generally uses only two electrodes, these placement locations may prove problematic in some apparatus or experiment designs due to the involved use of hands and feet during driving tasks. EDA may be used for indicating cognitive demand and stress in a simulation (Collet et al., 2014; Reimer and Mehler, 2011). Electrocardiogram (EKG) affords many opportunities to capture autonomous nervous system activity during driving simulation research and is achieved by using electrode arrangements. One use of EKG includes measurement of heart rate variability (HRV), defined as the variation in heart rate (beats per minute) over time interval (s). HRV is a reliable and relatively non-invasive psychophysiological secondary measurement for assessing psychological states such as anxiety or stress levels, focused attention, boredom, and drowsiness during simulation tasks (Fujiwara et al., 2018).

Subjective Measures

Traditionally, subjective measures have been used to gather insight into mental workload and relative stress levels experienced by participants during simulation studies (Brookhuis and de Waard, 2010). The most commonly used examples include the NASA Task Load Index, the Subjective Workload Assessment Technique, and the Rating Scale Mental Effort. A useful review of mental workload assessment criteria for subjective measures appears in Table 1, which may be employed for other constructs besides mental workload (Paxion et al., 2014).

Conclusions

- Many long-standing issues with simulation research remain unresolved, such as adequacy of fidelity and validity, participant selection, selection of measures, and simulator sickness.
- Fidelity measures the degree to which the simulation is realistic. Validity measures the extent to which the simulation and scenario assess and measure what they were intended to assess and measure. Both concepts are multifaceted with several subtypes, and each subtype should be carefully considered in turn.
- The identification of the target population and careful selection of participants is important for behavioral research in simulators. Gender, age, and other individual differences such as experience, personality, and ethnic group (s) should all be considered.
- Simulator sickness remains a major constraint on those conducting simulation research. Best practices utilize careful screening measures to limit the impact of simulation sickness, including questionnaires for similar conditions (e.g., motion sickness), as well as short trial runs in the simulator to test proclivities toward simulation sickness in the longer experimental simulations.
- Effective selection of measurement within the simulated scenario requires consideration of both the research question and validity concerns. Measurement can comprise of performance within the simulator itself (e.g., choices, response time, vehicle control metrics), as well as secondary measures, including but not limited to subjective measures, eye-tracking measures, and psychophysiological measures.

Fatigue and Crash Likelihood

Driving is a complex task that requires constant attention and a high level of focus. Fatigue impairs cognitive and physical performance and so greatly reduces the ability to drive safely and efficiently (Schmidt et al., 2009). In fact, fatigue is reportedly one of the leading causes of crashes worldwide. In the United Kingdom, fatigue is a contributory factor in some 20% of crashes and in North America the rate is reportedly around 40%. In spite of the magnitude of the problem, driver fatigue is scarcely mentioned in many road safety policies across the world. Limited countermeasures are in use and the effectiveness of these methods is still largely unknown.

Of course fatigue is also a problem in transport modes other than road transport. In aviation, pilot error is believed to be responsible for around 80% of plane crashes, and fatigue itself is identified as a factor in between 15% and 20% of these. Likewise, investigations into rail crashes routinely identify driver fatigue as a problem—studies in Europe, for example, show that between 20% and 25% of serious train crashes have been associated with drivers being drowsy, asleep or generally fatigued. Fatigue and sleep-related issues are clearly a matter of concern across many modes of transportation. The vast majority of the research into sleep and fatigue has emerged from studies of motor vehicle drivers; this is natural as this is the most commonly experienced context of fatigue and one whose consequences are seen on a daily basis.

Although there is widespread recognition that fatigue and sleep-related issues pose serious problems in transportation systems, it is immensely difficult to implement effective solutions, though experts in all sectors of the transport industry are working to achieve this. There are two main problems with fatigue. The first is that there is no internationally recognized or accepted definition of fatigue. Fatigue is a concept far broader than sleepiness—at essence it is about performance, and the competence of a driver to respond appropriately to the demands of the drive (Philip et al., 2005; Liu and Wu, 2009). Performance itself is a function of physiological impairment and psychological state. While this may sound straightforward, neither of these dimensions is simple to identify or measure.
